Pathogenesis of Acute Laryngostenosis in Measles.—Alfredo Villa describes an epidemic of measles occurring in Genoa in 1905 in which there were many cases of acute laryngeal stenosis, with several deaths. The epidemic increased for some six months. A relatively frequent complication was laryngeal stenosis and there was a resulting high mortality. There were three different periods of the disease in which the stenosis was observed; at the beginning, at the time of the eruption, and at the time of convalescence. The author believes that the stenosis was connected with an exanthema of the glottis, the eruption affecting the mucosa. This was a pure complication of the disease and not a mixed infection. When it occurred late in the case it was the result of a return of the measles eruption, if not of a renewed infection. The total number of cases observed in this epidemic was 269, in 45 of which the laryngeal complication was observed. Of these 32 occurred before or during the external eruption and 13 after it had passed away. The author describes two cases of great severity in one of which death occurred and an autopsy showed membrane in the larynx. This was examined and found to contain no Klebs-Loeffler bacilli, but only *Staphylococcus albus*. This appears to be an observation of importance, since if there is no true diphtheria present in such cases the little patients should not be exposed to diphtheria in a ward for the treatment of that disease.—*La Pediatria*, December, 1907.

Dystocia Due to Placenta Previa Aside from Hemorrhage.—Vincenzo Caliri says that there are many other causes of dystocia besides hemorrhage involved in the occurrence of placenta previa. The prognosis for the mother is rendered bad by many factors. The presentation of the fetus may be anomalous. The principal complications in this direction are breech and shoulder presentations. Earlier than this the malinsertion of the placenta, combined with the muscular contractions of the uterus, predisposes to abortion or premature labor. In most cases of placenta previa some sort of operative interference is required to effect delivery before the patient is exsanguinated by hemorrhage. All these procedures endanger the life of the mother, and render her liable to contract sepsis. Another cause of sepsis is incomplete contraction of the uterus due to inertia, and the formation of clots and thrombi in the uterine sinuses. Manual extraction of the placenta and membranes is another source of danger. Anemia is a source of mortality. Add to this the prematurity of the fetus, and we see that we have a formidable array of dystociæ aside from hemorrhage.—*Annali di Ostetricia e Ginecologia*, January, 1908.

Congenital Syphilis.—L. Tissier and Girauld have examined the forty suspected cases of syphilis confined during three months at the St. Louis Maternity. Of these there were nine abortions, twenty labors resulting in the delivery of fetuses dead and macerated, seven in which the infant was born alive in undoubted syphilitics, and three with living children in doubtful cases. These cases with examinations of the liver in dead children and the placenta in living children are tabulated by the authors. In none of the cases of abortion were the spirochetes found in the liver, although in cases of seven and eight months' gestation they are easily found. In macerated fetuses the spirochetes may disappear by autodigestion. Still eight times out of twenty-one macerated infants the organisms were found in the liver. They were never found in fetal or maternal placenta.—*Bulletin de la Société d'Obstetrique de Paris*, February 15, 1908.

Acute and Chronic Mastoiditis.—M. A. Broca says that otitis media is frequent with scarlatina, measles, and grippe. The ears of all children affected with these diseases should be carefully examined whenever there is a rise of temperature unconnected with the initial rash, or evidences of pain in the head. To prevent these complications the throat and nasal fossæ should be kept as nearly as possible in an aseptic condition by irrigations. When these cavities are affected the inflammation gains admission to the ear by the Eustachian tube and thus to the mastoid process. In the upper portion of the tympanic cavity which contains the long apophyses of the bones is found the aperture of the mastoid cells. This portion of the cavity is called the attic. Whenever you have cleansed the middle-ear and still see pus welling out from the attic you may be sure that it comes from the mastoid cells. In a subject with ottorrhea even slight tenderness on pressure over the mastoid process is an indication for operation, although there may be no swelling or redness of the postauricular region. The severity of the symptoms is not an index of the gravity of the bone caries. Neglect of slight mastoid symptoms exposes the patient to septic accidents and fatal intracranial lesions. In some cases formation of new bone occurs and the tympanic cavity is lessened in size by a protective process designed to obliterate the cavities of the apophysis. In every case of chronic otitis with mastoid symptoms the opening freely of all the cavities of the ear is demanded.—*Le Bulletin Medical*, January, 1908.

Book Reviews.

A Text-Book of Clinical Anatomy. For Students and Practitioners. By Daniel N. Eisendrath, A.B., M.D., Adjunct Professor of Surgery in the Medical Department of the University of Illinois (College of Physicians and Surgeons); Attending Surgeon to the Cook County Hospital, Chicago. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company, 1907.

This work is intended as a bridge between the anatomy usually taught in the first and second years, and the clinical work of the last two years of the medical course. As such it will be of service to the busy practitioner, who will be glad to have the surface anatomy and surgical and topographical anatomy brought clearly before him. This branch of the subject is as interesting as the ordinary first year anatomy with its interminable memorizing is dry and unattractive. The illustrations are an important feature of the work, and they are mostly original and are uncommonly well done. Further, the descriptive text, while adequate, does not overpower the illustrations. The book is one of the most serviceable of those dealing with this subject. It appeals to all—students and practitioners; physicians, surgeons, and specialists.

Technique Oto-Rhino-Laryngologique, sémiotique et thérapeutique a l'usage de l'Étudiant et du Médecin praticien. Par E. Escat. 322 Figures dans le Texte. Paris: A. Maloine, 1908.

This elaborate treatise is the result of thirteen years' experience of the author as a teacher of the practical side of ear, nose, and throat diseases. His object has been first to initiate the student into the special methods of investigation utilized in the diagnosis of ear, nose, and throat diseases, so that he may intelligently take up the clinical management of patients in this special field, and, second, to unfold to him the special therapeutic principles involved and acquaint him with the special surgical procedures. The ground covered is naturally familiar, but it may be said that the volume represents the very latest advances in this field. Escat has always had the reputation of being a clinician fertile in resources and very few will read his work without getting valuable diagnostic and therapeutic suggestions. The Table of Contents is very complete and any special topic can be easily referred to, but the addition of a good index would add greatly to the utility of the book.

On the Mechanism of the Physiological Action of the Cathartics. By J. B. MacCallum, M.D. Berkeley: The University Press, 1906.

This monograph of the recently deceased author contains an account of a long series of experiments made to determine the action of saline purgatives. The question concerning the exact seat of action of the purgative salts remains still unanswered. Whether, upon being absorbed into the blood, they act on the central nervous system is not known. There is no evidence to show that this is the case. It seems, on the other hand, from the experiments described, that they undoubtedly have an action on either the peripheral nervous mechanism or on the muscle cells themselves. It is impossible to prove that there is no action on the central nervous system, and at present it seems impossible also to prove whether the peripheral action is directly on the nerves or on the muscles.

The Operating Room and the Patient. By Russel S. Fowler, M.D., Professor of Surgery, Brooklyn Postgraduate Medical School; Chief Surgeon, First Division German Hospital, etc. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1907.

The second edition of this book has been enlarged by the addition of several chapters on the after-treatment of surgical patients. The course of aseptic wounds, of infected wounds, and of wounds of special tissues is briefly followed, and appropriate treatment is suggested for the complications that may arise in each case. It is to be regretted that advantage had not been taken of the reissue of the book to correct some faults in its older portion. For instance, boiling is still the only method mentioned for the sterilization of instruments and gloves, rectal anesthesia, so useful in many operations on the head and neck, is not described, and pure ethyl chloride is not mentioned among the anesthetics. Barring these minor faults, however, the book deserves favorable notice, as a useful guide to the operating room nurses, to the internes, and to the general practitioner, who may be called upon to carry out the after-treatment of surgical cases.

Diseases of the Nose. By Ernest B. Waggett, M.A., B.C. (Cantab.). Surgeon to the Throat and Ear Department of the Charing Cross Hospital, etc. London: Henry Frowde, Oxford University Press, 1907.

Diseases of the Larynx. By Harold Barwell, F.R.C.S. Surgeon for Diseases of the Throat, St. George's Hospital. London: Henry Frowde, Oxford University Press, 1907.

Both these works are issued in the list of "Oxford Medical Publications." They are printed on good paper, the illustrations are clear and they treat of their respective fields in a strictly up-to-date manner. They are among the best manuals for students beginning rhinology and laryngology it has ever been our pleasure to look over. The student will certainly get the impression that he is seated before his patient and that at his elbow is a friend who is telling him what to look for and how to use his special instruments to the best advantage, and, above all, how correctly to interpret what he sees. Both the writers are among the active teaching clinicians of London and their pages show that they have sought to emphasize the points which their experience as teachers has impressed on their own minds. We unhesitatingly commend these manuals to those who are taking up this special branch of clinical work.

Die Salzäuretherapie. Von Prof. Dr. Hans Leo. Berlin: Verlag von August Hirschwald, 1908.

In the present work Professor Leo gives his extensive experience with regard to the therapeutic efficacy of hydrochloric acid. He is a warm advocate of this medicament and considers it essential in conditions of subacidity of the stomach and principally in achylia gastrica. He always administers the hydrochloric acid in combination with pepsin, which he gives in large quantities. According to his experience patients with achylia gastrica do much better with the hydrochloric acid pepsin medication than without it. The book is very well written and can be warmly recommended.

Labyrintheiterung und Gehör. Von Dr. Heinrich Herzog. Mit 8 Tafeln und 28 Abbildungen im Text. München: J. F. Lehmanns Verlag, 1907.

In the space at our disposal it is difficult to review thoroughly this scholarly monograph on a topic in otology which is receiving much attention. The work opens with a general consideration of labyrinthine troubles, noting the difficulties in collecting facts regarding the early stages of suppurative disease, as cases are not then fatal and stating that reliance has had to be placed on cases fatal in the late stages because of some intercurrent malady which has generally been tuberculosis. Then follow chapters on the detection of unilateral deafness, etiology, pathological anatomy, clinical conditions found, and finally a summary of general conclusions. Some of these are herewith given, but the entire book is well worth the reading.

The destruction of audition by inflammation of the labyrinth results in a progressive narrowing of the tone-perception from the lower to the higher limits. Hence, in the diagnosis of a threatened labyrinthitis the determination of the lower tone-limit is most significant. Labyrinthine suppuration always causes complete deafness. An infection here begins as a diffuse serous or sero-fibrinous lesion. Retention of hearing always excludes a labyrinthitis. Circumscribed labyrinthine suppuration with retained hearing does not exist.

A Study of the Brains of Six Eminent Scientists and Scholars, belonging to the American Anthropometric Society, together with a description of the skull of Professor E. D. Cope. By Edw. Anthony Spitzka, M.D., Professor of General Anatomy, Jefferson Medical College, Philadelphia. Philadelphia: The American Philosophical Society, 1907.

The brains selected for special study were those of five eminent physicans and a naturalist of note. Microscopic appearances are considered. The general and special architecture of these brains is carefully studied and profusely illustrated by means of drawings and photographs. The weights of 137 brains of notable men and women are collected from records. A chapter is devoted to an exposition of the interrelation of brain and mind and the stages of its evolution. Some of the essayist's conclusions respecting *élite* brains are, in general, that the cerebral surface of such brains shows more numerous and prominent gyres; that the parieto-occipito-temporal area is, as a rule, most redundant; that the cerebrum is relatively more massive, the cerebellum relatively reduced, and that the callosa are larger than in ordinary brains. Marked individual differences between the six brains the essayist attempts to reconcile to prominent individual traits exhibited during life.

Society Reports.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 4, 1908.

Dr. Charles L. Dana, the retiring President, in resigning the chair to Dr. B. Sachs, the President-elect, expressed his pleasure at the successful work of the Society during the past year and his gratification at the support which had been given him in his efforts to make the Society a working organization.

President's Address.—Dr. B. Sachs, the President-elect, expressed his deep appreciation of the confidence his fellow members had reposed in him by electing him a second time to the presidency of this Society. After referring to the good work done by the Society in the past, and urging the members to continue to give their best efforts in the future, the speaker said that if he read the signs of the times correctly, we were passing in neurology and psychiatry from a period in which we were swayed by purely anatomical and physiological considerations, from an era in which localization and the clinical definition of disease played a most important rôle, to an era in which the etiology of disease and of disease-processes would claim our chief attention. We would be more interested in the questions of the bearing of heredity upon the development of disease: in the question of degenerative disorders, of bacterial infections, and in the aids given to diagnosis and treatment by a study of the blood, of the cerebrospinal fluid, of the efficacy of organic extracts, etc. Changes in the ductless glands and their relations to various conditions in which neurologists were interested would also come up for special consideration, and there was much yet to be done in connection with the proper recognition and treatment of brain abscess, tumors at the base of the skull, and even in the matter of spinal surgery. He hoped that the members would see fit to take some definite action, either independently or in conjunction, if necessary, with the Academy of Medicine, in order to remedy the evils of medical expert testimony. As a body we should make a desperate effort to wipe out the stigma resting upon all of us because of the abuses which had grown up in our medicolegal procedure. It was a fact which no one of us would deny that the medical expert at the present time was mentioned with a sneer, and the slur fell heaviest upon us, because in the majority of instances the neurologist and alienist was the medical expert at whom these shafts of public criticism were directed. It would be a great tribute to the standing of this Society if its deliberations would lead to the creation of an impartial medical commission to whom the court would submit the question of sanity or insanity in any given case.

A Case of Suspected Huntingdon's Chorea.—Dr. Allen Starr presented this case. The patient was a negro, 26 years old, who had apparently enjoyed perfect health until his seventeenth year. His family history was unimportant and contained no facts bearing on the present case. The patient was born in Eastern Maryland, and a fairly good knowledge of his ancestors was obtainable. About nine years ago his mother noticed that he was awkward in his movements. This was first noticed in the hands, and gradually extended to the arms, legs and body, and finally affected the muscles of the jaw and mouth. In connection with this loss of control, there were peculiar arythmical movements of the muscles. There was a dropping of the hands, with a certain amount of contraction of the wrist, together with a shuffling, peculiar gait with high, irregular steps. On account of the involvement of the muscles of the mouth and jaws he was unable to make himself understood, although his mother stated that she still could understand him at times. On attempting to speak he made extraordinary grimaces. He apparently understood what was said to him. Accompanying the physical symptoms, there had been a gradual mental impairment. When he was sixteen years old, according to his mother, he could read and write and was fairly bright at school; now he was stupid and took little interest in what was going on around him. There was no nystagmus: no ankle clonus; no Babinski; no sensory symptoms. The knee jerks were slightly exaggerated. Dr. Starr said that on account of the intentional tremor he was first inclined to regard the case as one of progressive multiple sclerosis, but Dr. Richard H. Cunningham, who saw the patient at the Vanderbilt Clinic, identified it as one of Huntingdon's chorea. Personally, Dr. Starr said, he had never seen an example of that affection, and he could find no record that it had ever been observed in a negro, nor was there a family record of the disease in this instance.

Dr. Richard H. Cunningham said that in 1893, while practising in the South, he had under his care a family affected with this trouble. They were not negroes, however. The history obtained was that the paternal grandfather died of apoplexy. The father developed these peculiar choreic movements at about the age of 30, although he lived until the age of 56. He was the father of six children: two of these were apparently healthy; the other four, two of them girls and two boys, all suffered from this disease. In the eldest son it began when he was eighteen years old, and when Dr. Cunningham saw him he was 25. In the next brother and in one sister it began at the age of 14, and in another sister at the age of 18. One paternal aunt had also developed this trouble when she was about 20 years old. They all presented these typical incoordinate movements, and in the eldest son the speech was involved as in the present patient. In the other children the speech was affected, but not so noticeably. The progress of the disease was apparently extremely slow. The speaker said he had lost sight of the cases after they had been under his observation about a year.

Dr. Edward D. Fisher said he had under his observation at present a family, several members of which had suffered from Huntingdon's chorea. The father had died of the disease. One brother, while suffering from it, shot himself, and there were two other brothers who were now suffering from it. While the case shown by Dr. Starr certainly suggested Huntingdon's chorea, it was also somewhat suggestive of a double hemiplegia, with degeneration and athetosis. The reflexes in this case were a little more marked than those usually observed in Huntingdon's chorea. In the cases he had seen the disease began later in life than in this case.

Dr. Pearce Bailey said that in a case of Huntingdon's chorea lasting as long as this one, the characteristic mental changes should be more pronounced. The speaker said that in one of the only two cases of Huntingdon's chorea he ever saw the mental condition became such that the patient had to be committed to an institution. The slow, synergic movements in this case, however, were quite characteristic of Huntingdon's disease.

Dr. Charles L. Dana said that in a case of Huntingdon's chorea which had been under observation for a year or two at Bellevue Hospital, the patient died and the brain examined. In that instance, as in those referred to by Dr. Fisher, the disease developed much later in life than in this case. The patient had the characteristic clonic movements and the peculiar gait, but there was no disturbance of speech. In the case shown by Dr. Starr there were certain symptoms which were not usually present in Huntingdon's chorea; there was a distinct tremor of the limbs, and tonic movements of the muscles which suggested a spastic tic. On the whole, however, he thought it could be classed as a case of hereditary chorea of the Huntingdon type.

A Case for Diagnosis.—Dr. Edward D. Fisher presented this case. The patient was a man, 45 years old, who for the past three years had noticed a gradual weakening of the right side of the body, especially involving the hand and arm, and later the leg on the corresponding side. Accompanying this loss of power, there was an excessive intentional tremor affecting the muscles of the right hand and arm. The speaker said he was first inclined to regard the case as a slowly progressive lesion of the crus cerebri, but an examination of the left arm showed a distinct wasting of the muscles below the elbow, especially involving the intrinsic muscles of the hand, with considerable loss of power. This condition, according to the statement made by the patient, was of much longer standing than that on the right side. The patient denied syphilis. The pupils showed some irregularity; the reflexes were exaggerated; there was no change in the electrical responses; no disturbance of speech; no nystagmus. Dr. Fisher thought the case was possibly an irregular type of amyotrophic lateral sclerosis.

Dr. Starr called attention to the fact that the atrophy of the left arm as well as the contracture of the fingers pointed to a lesion of the ulnar nerve on that side.

Dr. Frederick Peterson said the case shown by Dr. Fisher reminded him somewhat of the condition known among the French and German writers as Benedikt's syndrome, which consists of a hemiplegia on one side, with clonic spasm or tremor and oculomotor paralysis of the opposite side. The condition had been described by Oppenheim and Charcot under the name of Benedikt's symptom-complex or syndrome.

Nerve Bridging, with a Report of a Successful Case.—By Drs. Alfred S. Taylor and L. Pierce Clark. The patient was a child upon whom the operation of nerve bridging for brachial birth palsy had been done two years and eight months ago. At the time of the operation the child was eleven months old and had complete paralysis of the left arm as the result of a rupture of the brachial plexus. Upon operation, it was found that the distal portion of the nerves could not be brought into apposition with the nerves as they emerged from the spinal foramen, and nerve bridging had to be resorted to over a space of 2 cm. Six months after the operation a certain amount of motion was noticed in the triceps and the pectoralis major, and the fingers showed the redness that was characteristic of trophic changes. Eleven months after the operation there was considerable motion in the arm, and the trophic disturbances had nearly disappeared. At the expiration of two years and four months the child was able to raise the arm, and since October, 1907, the increase in the degree of motion in the muscles of the affected extremity had been very marked. The child could now bend the elbow, and had fairly satisfactory use of an arm which was at one time absolutely palsied.

Dr. J. Ramsay Hunt said that in one case of attempted nerve bridging that had come under his observation in a child aged 20 months, the wound unfortunately became infected, suppurating for several weeks, and the arm was left in a worse condition than before the operation.

Demonstration of Patient Wearing a New Plate for Defect in Skull.—Presented by Dr. Charles A. Elsberg (by invitation). The patient was a boy of 10 years, who was admitted to Mt. Sinai Hospital on May 22, 1907, with the history that half an hour before admission he had fallen out of a second story window. He was brought to the hospital in a semi-conscious condition, with tonic and clonic convulsions of the right side of the face and of the right upper extremity. There was a large hematoma in the left parietal region. At the operation, which was done by Dr. Howard Lilienthal, there was found a depressed fracture, with considerable splintering of the fragments and an irregular fissured fracture running across the median line to the right parietal region. A large amount of bone had to be removed. There was an extensive extradural blood clot. Forty-eight hours after the operation there was complete paralysis of the right side of the body. In the belief that there was blood underneath the dura, the boy was again anesthetized, the wound reopened, and the dura incised. A very profuse hemorrhage followed, which could be controlled only by tight packing with gauze. The patient recovered from this operation after a long and complicated convalescence, and was finally left with a large defect of the skull. There was a depression so large and deep that the greater part of the closed adult fist could be inserted into it. The deformity was a very ungainly one, and the parents of the child were anxious to have something done to remedy it. On August 26, 1907, Dr. Elsberg made a large flap over the defect in the skull, turned down the skin, and inserted an aluminum plate of his own design. The result was very satisfactory. The wound was entirely closed, and healed by primary union. The boy was discharged cured on September 21. The splint employed in this case was made of aluminum, which could be made into the shape desired without trouble. The plate had a number of arms which could be cut off at different lengths to fit into the irregular defect. The ends of the arms were split longitudinally for a short distance, and one part of the arm then bent downwards. The entire plate was then bent to conform to the general shape of the skull. When in place, one part of the extremity of the arm rested on the outer surface of the skull along the edge of the defect; the other part rested against the cut edge of the skull along the margins of the defect. The plate was kept in position by a few catgut sutures which attached the horizontal part of the extremity of each arm to the periosteum. The advantages of this plate were the following: It formed a perfect arch, and the more pressure that was put upon the arch from the outside, the firmer and stronger it became. It remained in place and made a firm support, bridging over the defect of the skull. It was easily made and easily inserted, and could be bent into any shape desired. It had none of the faults of plates which rested on the outside of the skull and were apt to shift their position, nor of plates put inside of the bone, which rested directly upon the dura or the brain.

Grave Chorea and Its Relation to Septicemia.—Dr. B. Sachs read this paper (see page 505).

Dr. Charles L. Dana asked Dr. Sachs how he differentiated between this form of chorea, and that known as chorea insaniens. He generally observed several of the latter type of cases in the hospital each year, and while they were usually looked upon as of infectious origin, that fact had not been demonstrated as perfectly as in the cases reported by Dr. Sachs.

Dr. M. Allen Starr said that he had seen two cases of ulcerative endocarditis, with choreic movements of the face and extremities. The endocarditis was of definite bacterial origin, and the cases were a good illustration of the fact that any acute bacterial infection may in certain individuals produce choreic movements. That view might be taken in connection with the cases reported by Dr. Sachs. In both there was a general streptococcus infection, of which the chorea was apparently the chief manifestation. It was questionable, therefore, whether we were really dealing with a new toxic disease or merely a manifestation or prominent symptom observed in certain infections.

Dr. Nathan E. Brill asked Dr. Sachs why he used the term "toxic chorea" in reference to this disease. As yet it had not been demonstrated that a toxemia was the cause of chorea, nor yet could it be proven that in the class of cases reported by Dr. Sachs the toxins rather than the mechanical effects of the bacteria in the cerebral capillaries were the causative factors. It would seem to be more in harmony with the fact that in one of Dr. Sach's

cases there was a distinct staphylococcemia, to call this class of cases "chorea associated with septicemia," or "bacteriemic chorea," rather than toxic chorea. Pathologists had called the invasion of the circulatory system by bacteria septicemia. The tendency was now to limit the term more definitely and call such a condition "bacteriemia." If this condition were associated with chorea, either etiologically or not, we had the condition which Dr. Sachs wished to emphasize, but in that respect that form of chorea would differ but little, perhaps mainly in its clinical picture, from the chorea associated with what was called "acute articular rheumatism." It was now generally conceded that acute rheumatism was a generic term covering many conditions associated with acute inflammatory joint changes; that the most of these were regarded as the result of an acute infectious process, some with known portals of entrance, as the tonsils, others of unknown source. It was also a fact that endocarditis and chorea were accompaniments of this class of diseases, and likewise that in some forms a bacteriemia had been established. In some cases, a diplococcus tenuis, and in others a streptococcus tenuis had been recovered from the blood. The fact that in acute articular rheumatism, in which chorea and endocarditis might play a part, no bacteria had been isolated from the blood, ought not to be considered to prove that no bacteria were present in the circulatory medium, but rather, reasoning by analogy, that thus far the cultural means at our command had been inadequate or insufficient to recover the offending organism. In the light of this view, Dr. Sachs' cases might differ but little pathologically from the class of chorea associated with acute rheumatism—the clinical form, perhaps, being modified by the varying type and virulence of the invading organism. We might say, however, that Dr. Sachs had established a fact; namely, that certain cases were associated with a distinct bacteriemia. Dr. Brill did not understand that Dr. Sachs desired to establish a new form of chorea.

Dr. Sachs said he had not the slightest intention of trying to establish a new disease. His only idea was to place on record these very unusual cases, which he recognized as a special form of chorea associated with an intense general infection, of which the chorea was the most prominent symptom. In some of these cases the infective agent was the staphylococcus, in others the streptococcus or some other agent, and one object in keeping them apart was that in a therapeutic way it would help us to recognize them as very serious infections. In reply to Dr. Dana's question as to the connection between this form of chorea and chorea insaniens, Dr. Sachs said that in recent years he had dropped the term chorea insaniens, and he did not consider it a very useful one from either a clinical or pathological standpoint. The term was applied usually to the more chronic forms of chorea, associated with mental deterioration, rather than to cases of acute origin associated with high fever.

Dr. Dana said he had seen cases of chorea insaniens which corresponded very closely to those reported by Dr. Sachs. A few of the patients had recovered. He could recall no good description of this type of chorea in literature.

Dr. Sachs, in reply to Dr. Brill, said that in calling these cases toxic chorea he had not been guided entirely by his own view of the etiological factors concerned in their production. The symptoms were supposed to be due to a toxin, but whether always and distinctly bacteriemic or not he could not definitely decide.

Officers.—At the annual meeting of the Society in January the following officers were elected for the ensuing year: *President*, Dr. B. Sachs; *First Vice-President*, Dr. J. Ramsay Hunt; *Second Vice-President*, Dr. Smith Ely Jelliffe; *Corresponding Secretary*, Dr. Max Mailhouse; *Recording Secretary*, Dr. E. G. Zabriskie.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, February 17, 1908.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Report of the Committee on the Death of Dr. Henry P. Loomis.—Dr. Charles H. Knight, Chairman. (Read by the Secretary.)

Report of the Committee on the Death of Dr. Robert W. Taylor.—Dr. Edward B. Bronson, Chairman, presented the following report.

Mr. President: At your direction we call the attention of the association to the recent death of our late lamented colleague, Dr. Robert William Taylor.

It is wholly fitting that a halt should be called in our proceedings to do honor to him, one of the most distinguished of our members. To us was rendered what was probably his last public service in that domain of medicine in which his lifework was mainly engaged. Even then, hampered as he doubtless was, and with something of his old-time vigor abated, through the encroachments of the fatal malady to which he shortly after so suddenly succumbed, there was still in evidence that sincerity of purpose, zeal and earnestness which had always characterized the spirit of his work.

Though chiefly pre-eminent in the field of that most intricate and absorbing of all enigmas of medical research, syphilis, Taylor's name was also famous for signal services looking to the relief of those other ills of erring flesh, the hideous progeny of lust and folly. Through the welter of these afflictions of humanity, involving as they do the innocent as well as the erring, he waged a lifelong combat, seeking the roots and remedies of evil and bearing aloft the torch of hope.

Nor did these Augean labors limit the range of his activities. Beginning his professional career at a time when more than now were associated in a common specialty, both venereal diseases and the general affections of the skin, his interest in and contributions to dermatology were most valuable and occupied him to the end.

The list of his published works in these fields of research is an extensive one. They have had great influence in the medical world, and many of them were translated and published in foreign tongues. One of the earlier of his better known contributions thus honored was a paper entitled "On Dactylitis Syphilitica, with Observations on Syphilitic Lesions of the Joints," published in 1871. The subject matter here presented was a field comparatively unexplored, and this paper attracted attention far and near. In 1879 Taylor's name became associated with that of Bumstead in joint authorship of the fourth edition of the "Pathology and Treatment of Venereal Diseases." Under the same title, in 1895, after Bumstead's death, Taylor rewrote the book, which was now published under his own name and independently. Subsequent editions (the third appearing in 1904) bore the title, "A Practical Treatise on Genitourinary Diseases and Syphilis." This work took high rank as a textbook, and still remains a standard authority. In 1897 appeared his "Practical Treatise on Sexual Diseases of the Male and Female," of which a third edition was published in 1905. Another notable work by Taylor was his "Clinical Atlas of Venereal and Skin Diseases," and, in addition to these works, there is a long list of papers on many themes relating to those subjects with which he was specially concerned, many of them of great value and all elaborated with exemplary care.

Beside his literary labors should be placed his long service at Charity (now City) Hospital, where he trod in the footsteps of those earlier masters, Van Buren and Bumstead, together with his public teachings as professor in the chairs either of venereal or skin diseases, first at the Woman's Medical College and later at the College

of Physicians and Surgeons, as well as at the University of Vermont.

In all of these labors his work was indefatigable. With a catholic spirit, he combined the temper of the conservative. Broad in exposition of the views of others, the expression of his personal judgment was tempered with caution and reserve.

But, while acknowledging the worth of his intellectual achievements, let us not forget the amiable qualities of the man. By nature impulsive, while sometimes hasty of speech and on occasion resentful of real or fancied injuries, Taylor was a loyal friend and an agreeable man to meet. In his manner, with its air of cordiality, cheeriness and bonhomie, there was a something that savored of a personal compliment. He liked to be liked, as, in his home life he loved to be loved. The pity of it is that in his home, where all should have been happiness and content, one deep shadow of affliction succeeded another, till in his latter days lonely grief tinged his life with sombreness and doubtless accelerated its end. So, in our acclaim over the triumphs of an accomplished career, a successful life, there intrudes the note of pathos, an undertone of sympathetic regret. Peace to his ashes! Lasting honor to his shade!

(Signed) E. B. Bronson,
Chairman.

James R. Hayden.

Address by the Retiring President.—Dr. Thomas E. Satterthwaite. (See page 381.)

Metaplasia of the Appendix Vermiformis, and a New Diagnostic Point.—Dr. Robert Tuttle Morris, the president-elect, said the time had now come to classify appendicitis cases under four separate and distinct heads: 1 Normal involution, beginning with a metaplasia of the lymphoid and submucous coats and ending with connective tissue replacements of all coats. During a part of the involution process, these patients suffered from local and reflex disturbances, and they formed, probably, the larger part of all patients suffering from the presence of the appendix vermiformis, although the cause of their trouble was commonly overlooked, or else the cases were confused with forms of Class 2, namely, infective appendicitis. Under Class 3 the speaker included the congestive type of appendicitis occurring as the result of some obstruction of the blood or the lymphatic circulation, and under Class 4 those cases due to congestion secondary to some infection, such as tuberculosis or cancer. When the appendix was undergoing a normal involution process, with replacement of its lymphoid coats by connective tissue, digestive disturbances and various local neuralgias might be due to irritation of nerve filaments entrapped in the new connective tissue. In those cases there might be no tenderness at McBurney's point, but there might be persistent tenderness at a point which Dr. Morris described as follows: Draw a line from the right anterior superior spine of the ilium to the navel. On this line, an inch and a half from the anterior superior spine, we found McBurney's point. Tenderness on deep pressure at this point gave presumptive evidence of an irritative process in the vicinity of the appendix vermiformis, but tenderness on superficial pressure at this point might mean irritation of sensory nerves of the abdominal wall, and the irritation might be due to causes ranging from hysteria to toxemia. McBurney's point was of great diagnostic value to physicians who possessed a considerable degree of collateral knowledge, aside from their familiarity with the symptoms of appendicitis. At a point situated an inch and a half from the navel we found another tender point of definite diagnostic value. McBurney's point and the point here described were six inches or more apart in the adult of average proportions. The point here described had reference to the right lumbar ganglia of the sympathetic nervous system, and notable tenderness of these ganglia had a diagnostic value which might briefly be placed in classification under the following general heads: 1. In the early stages of an acute infective process of the appendix, the right lumbar ganglia were tender and the left lumbar ganglia were not tender. The left lumbar ganglia might be described for diagnostic purposes as lying an inch and a half to the left of the navel. Under these circumstances the point here described was of secondary importance, while McBurney's point was of prime importance. 2. When an acute inflammatory process of the appendix had subsided, leaving a mucous inclusion or scar tissue, there might be no tenderness on pressure at McBurney's point, but there was tenderness at the point here described, and no tenderness at the point of the left lumbar ganglia. When the appendix was undergoing a normal involution process, with replacement of its lymphoid coats by connective tissue, digestive disturbances and various local neuralgias might be due to irritation of nerve filaments entrapped in the new connective tissue. In these cases there might be no tenderness at McBurney's point, but there was persistent tenderness at the point here described. There was no tenderness at the point of the left lumbar ganglia. When the appendix was congested without the presence of infection, as in many cases of loose kidney, there might be little or no tenderness at McBurney's point, but there was persistent tenderness at the point here described. There was no tenderness at the point of the left lumbar ganglia. The point described would also be found of value in every-day diagnostic work for differentiating between irritations of appendix origin and those of pelvic origin. In the latter class of cases, both right and left lumbar ganglia were tender. To recapitulate: Right lumbar ganglia tender, alone—appendix trouble. Right and left lumbar ganglia tender, together—pelvic trouble. Neither right nor left lumbar ganglia tender—trouble somewhere cephalad from pelvis and appendix.

Dr Robert F. Weir said that Dr. Morris' views upon the involution of the appendix were to a certain extent familiar to him. While this involution process might to a certain degree inhibit infectious invasion by partial obliteration of the lumen of the appendix, the speaker said he did not understand how it could prevent it entirely until the obliterative process was complete. As to the new diagnostic point described by Dr. Morris, it certainly afforded an interesting basis for further investigation, and if the writer's deductons were confirmed by others, it would place the discovery upon a par with the celebrated McBurney's point, upon which, however, surgeons were now inclined to lay less stress than formerly, not because good had not come out of it, but because so many had misinterpreted the special value of Dr. McBurney's suggestion. Its great importance was that a finger-point pressure was the most reliable method of eliciting pain in cases of appendicitis, but the particular point justly known by McBurney's name was not as accurate as it was supposed to be for determining the true situation of the appendix, which commonly occupied an area corresponding to a section of a circle of about half an inch radius, stretching from the crest of the ilium to Poupart's ligament. Dr. Weir said that the first and second lumbar ganglia to which Dr. Morris evidently had reference in connection with the diagnostic point he had described, did not receive, or distribute impressions from the region of the appendix at all, but their sensory reflexes were to be found considerably lower down, over the thigh. Hence any painful nerve manifestations through the sympathetic system about the navel must spring from the lower dorsal nerves. In conclusion, Dr. Weir believed if the painful spot described by Dr. Morris was confirmed by larger observation it would rather be found to be due to the remains or results of an infectious process rather than to a direct pressure upon a lumbar ganglion. In two instances in which, since the publication of Dr. Morris' paper on this subject, he had encountered

a dormant appendical trouble, he had failed to find the Morris tender spot, though by Meltze's elevation test he had clearly defined a tender appendix overlying the elevated psoas muscle. It is only fair to say that this test has not been verified in these cases by an operation.

Dr. Algernon T. Bristow of Brooklyn, said the normal involution of any organ which had become useless because it had become functionless was something which could not be measured by the lifetime of any one man; it was not measured by decades nor centuries, but by thousands of years. Furthermore, it was a strictly normal process, and we could not associate inflammatory processes with what we termed normal involution. The two were entirely distinct entities. In man we had a small appendix, possessing certain anatomical peculiarities; the first of these was its relatively poor blood supply, which favored inflammatory changes. Again, we had an organ that was poorly drained, and with these two, plus the introduction of infective material, we had the three factors which went to produce the process called appendicitis. The speaker said he seriously objected to the statement made by Dr. Morris that chronic obliterative appendicitis should be looked upon as a normal involution process. Since we always found a round cell proliferation in the submucosa and increase in connective tissue, we had no more right to speak of that as a normal involution of the appendix than we had to speak of cirrhosis of the kidney as a normal involution of that organ. The same was true of the liver. The proliferation of connective tissue in these various organs was a disease process, and not a process of normal involution. In regard to the importance of recognizing chronic obliterative appendicitis, and the symptoms it gave rise to, the speaker said that Dr. Morris might go even a little further than to refer to the condition of those patients as one of simple discomfort. They were often treated as cases of chronic dyspepsia, gastric catarrh, colitis, etc., but when we came to examine them we found this condition of chronic inflammation of the appendix, which occasionally does, although rarely, explode into an acute process. The proper treatment of those cases was not altogether a question of comfort; it was really a question of health versus invalidism. Although the removal of the appendix in these cases was not a life-saving operation, the retention of the organ kept these patients ill, and it was sometimes astonishing to see the rapid improvement in health after operation. Some of the most happy results he had seen after removal of the appendix were in these very cases of chronic cirrhotic appendicitis.

Dr. Alexander B. Johnson said that, while he had no personal knowledge of the new diagnostic point in appendicitis described by Dr. Morris and had had no opportunity to verify it, he felt inclined, in view of what we already knew of Dr. Morris' work in connection with this general subject, to take it seriously and test its value in the future. The speaker said it so happened that a very large proportion of his cases of appendicitis were of the acute infectious type, although a certain proportion belonged to the class that the reader of the paper had very properly described as due to normal involution of the appendix. Both involution and evolution went on in the individual, just the same as they did in the race, but he could not quite agree with Dr. Morris that this involution of the appendix went on with but little risk of an infectious process. In a very large proportion of cases that was doubtless true, but he had seen a goodly number of cases of appendicitis in which the major portion of the distal end of the appendix had undergone involution, with an inflammatory process at the base, and this pent-up infectious focus had been prevented from emptying itself into the cecum by the more or less strictured condition of the organ. Further, he had seen a perforated appendix in which the major portion of the organ had undergone an apparently normal involution. It occasionally happened that infectious appendicitis, with perforation, had occurred in tuberculosis of the appendix, and the speaker recalled one case where it happened in cancer of the appendix. Dr. Johnson said it had been his practice for a number of years past, in operating on women for pelvic conditions, to remove the appendix at the same time, whether it had given rise to symptoms or not, and in a fairly large proportion of these cases the appendix was found to be undergoing a normal involution. In only a small proportion of those cases had the patients given any history of symptoms referable to the appendix, although in some instances they might have been masked by the pelvic symptoms.

Dr. Franz J. A. Torek said he had been aware for a number of years that there was a tender point at the place described by Dr. Morris, but he was inclined to look upon it as of less diagnostic value than the reader of the paper. He had found it present in cases of appendicitis of the ordinary type, and he would not limit it, as he understood Dr. Morris to say, to cases of the normal involution type only. He had met with it in a case where there was no trouble with the tubes or ovaries, and where the appendix had been removed four years before. The distance from the anterior superior spine to the umbilicus was usually given as from seven to eight inches; it might be only half that distance, and he had repeatedly found it to be four inches; under such conditions McBurney's point and that described by Dr. Morris might be very close together. He would not limit the exact location of this point to an inch and a half from the umbilicus; the distance might be a little more or less, the same as with McBurney's point.

Dr. John B. Walker said his own views and conclusions in regard to this subject coincided very closely to those of Dr. Johnson. He could recall quite a number of cases of appendicitis of the ordinary type in which the appendix was obliterated, and in which the disease was limited to the unchanged tissue that remained. In the chronic cases of obliterative appendicitis the patients ofttimes complained of a good deal of pain, which might even be severe enough to prevent them from working, and this condition, to people who had their living to earn, was a serious matter. In regard to the point of tenderness described by Dr. Morris, the speaker said he had had no experience with it. In one or two instances the point of tenderness had been nearer the umbilicus than to McBurney's point.

Dr. Charles H. Peck said he would await with interest further observations regarding the diagnostic accuracy of the point described by Dr. Morris. He had several times been unable to differentiate between trouble in the right tube and in the appendix, and if this point in diagnosis would prove an effective help in those cases, it would certainly be of great value. The speaker said he was inclined to agree with Dr. Bristow that the partial obliteration of the appendix that was not infrequently observed should be looked upon as the result of a chronic inflammation rather than as representing a true normal involution.

Dr. Albert A. Berg said the meaning of pain in the lower right quadrant of the abdomen was very often obscure. If the appendix or the diseased adnexa were the organs at fault, it was comparatively easy, in most instances, to make the correct diagnosis. There were, however, many other structures in that particular area which frequently were the seat of disease, and the recognition of which it was most important to establish. In this connection, the speaker said, he particularly had in mind pathological conditions affecting the kidney and the lower portion of the right ureter, and he could recall instances where patients whose symptoms were unrelieved by an appendectomy were subsequently found to be suffering from a uretral stone, or a kink in the ureter, or trouble in the right kidney. Dr. Berg said that to attempt to make the diagnosis in these cases by the pain or tenderness only seemed to him to be taking a step backwards. It required

more than mere local tenderness or local pain in the lower right quadrant of the abdomen to establish a diagnosis. There were inflammatory conditions of the cecum which not infrequently excited pain in the lower iliac region, and he knew of one instance where three operations had been done for the relief of such pain without success. In regard to the liability of an acute infectious process with gangrene and perforation occurring in the case of so-called normal involution of the appendix, the likelihood of such an attack would probably be very slight if the process of involution was a uniform one, *i.e.* involving the entire lumen of the appendix uniformly, otherwise—*i.e.* if the process of involution was more advanced in some parts of the appendix and less in others, it was fair to assume that stricture formation would be apt to result and thereby increase rather than diminish the danger of infection, with consequent gangrene and perforation.

Dr. Morris, in closing the discussion, said that in cases of infective appendicitis, associated with the presence of hyperplastic connective tissue, similar to that occurring in fibroid degeneration of the appendix, we had a history of previous attacks of acute appendicitis, and the condition was entirely distinct from that observed in cases occurring in the course of fibroid degeneration of the organ. In the recurrent infective type of appendicitis we had scar tissue resulting from a previous acute attack; these patients usually complained of numerous attacks of pain which were not sufficiently severe to put them to bed, and the tenderness was not so apt to be persistent. The speaker said that, while he was not in a position to offer an entirely satisfactory explanation of the cause of the point of tenderness he had described occurring in the course of fibroid degeneration appendicitis he did not consider it as secondary to the presence of infectious material carried by the lymphatics, and was more inclined to regard it as the result of sympathetic connection; the subject had not yet been worked out, excepting in a clinical way. He was willing to admit that normal involution was not exactly the right term to apply to this process going on in the appendix, and for that reason he had added the word hyperplasia. That still did not cover the ground. Fibroid degeneration was probably the preferable name for the condition.

College of Physicians of Philadelphia

At a stated meeting, held March 4, Dr. Joel E. Goldthwaite of Boston presented, by invitation, a communication entitled "Our Present Understanding of the Non-Tuberculous (Rheumatic) Diseases of the Joints." He raised the question whether what at the present time is designated rheumatism is in reality a definite clinical entity and not merely a symptomatic group of disorders. He pointed out that multiple arthritis may develop in the course of a number of infectious diseases, such as influenza, scarlet fever, typhoid fever, pneumonia, and be due to numerous microorganisms. In the treatment, therefore, primary consideration must be given to the underlying condition. In this connection the tonsil especially should be carefully investigated. Attention should be directed also to the gastrointestinal tract, and infection from this canal prevented. In some instances speedy relief will follow evacuation of accumulations in the accessory sinuses of the nose, the antra and the ethmoidal cells. Strain and faulty posture likewise may give rise to articular disease. This is sometimes observed in the knees, at times also in the wrists. It is not generally appreciated that the pelvic joints possess a certain degree of mobility and that, as a result of strains, such as result from labor and heavy lifting and the like, displacements may occur that give rise to pain in various situations, and sometimes simulating sciatica. Great relief can be afforded by intelligent manipulation. As a result of faulty posture in early life the scapula may acquire an angular deformity at the origin of its spine, so that movement of the shoulders is attended with pain. This can be corrected by surgical measures.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, State of Oregon.

Portland, January 7, 8, and 9, 1908.

PHYSIOLOGY.

1. What is tidal air; complemental air; supplemental air; residual air?
2. State function of carbohydrates.
3. What is meant by tetanus?
4. Describe and give formation of lymph.
5. Define cardiac circle.
6. What is the structure of the stomach? Describe its coats.
7. State variety of secreting membranes and where found.
8. Describe physiology of hearing.

ANATOMY.

1. Describe the elbow joint.
2. Describe the posterior triangle of the neck, giving parts found in it.
3. Describe in detail, ligation of the subclavian artery in the third part of its course.
4. Name the principal branches of the fifth cranial nerve.
5. What anatomical structures lie beneath Poupart's ligament?
6. What parts would be divided in amputation through the middle of the arm?
7. Describe the common bile duct.
8. Give the blood supply of the eyeball.

HISTOLOGY.

1. Give the histological formation of a long bone as seen in a cross section.
2. Name the principal forms of connective tissue.
3. Trace the course of the urine from the capsule of Bowman to the pelvis of the kidney.
4. Name the corpuscular elements in the blood.

CHEMISTRY.

1. What is an element, and how many are there?
2. Define matter, force, energy, giving an example of each.
3. Define chemical affinity, and how does it differ from other forces?
4. What points are to be considered and substances to be determined in the examination of normal and abnormal urine?
5. Describe the tests for bile, blood, pus, and urea in urine.
6. Give tests for detection of morphine.
7. Give tests for arsenic.
8. Given a suspicious powder, how would you treat it for strychnine?

MATERIA MEDICA AND THERAPEUTICS.

1. Name some of the digestive ferments and when indicated.
2. What chemical changes take place when mineral acids are taken into the stomach?
3. Give the physiological action of phosphorus.
4. Name some of the preparations of arsenic. Give dose of each.
5. Name two stimulant expectorants. Give indications and dose of each.
6. Name some of the antagonists and synergists of mercury.
7. What are the therapeutic indications for digitalis and amyl nitrite?
8. Name two motor depressants. Under what conditions are they indicated?

DIAGNOSIS.

1. Give diagnosis of Pott's fracture.
2. Give diagnosis of gallstones in the gall-bladder.
3. Give diagnosis of stenosis of the pylorus.
4. Given a case, age 16, two months before had a fracture of the upper third of the femur with union, deform-

ity and two inches shortening. Make diagnosis. What causes the shortening?

5. Give diagnosis of abscess of liver.

6. Differentiate measles and scarlet fever twenty-four hours after the eruption first appears.

7. How could you diagnose green stick fracture of the radius in a child two years old?

8. Give symptoms of stone in the male bladder.

PRACTICE OF MEDICINE.

1. Give causes and symptoms of acute endocarditis.

2. Give symptoms and pathology in acute pleurisy.

3. How would you treat a case of acute lobar pneumonia?

4. Differentiate symptomatically asthma from edema of the glottis.

5. Differentiate a syphilitic from a tubercular ulcer of the pharynx.

6. Give the pathological anatomy in acute parenchymatous nephritis.

7. Diagnose symptomatically cerebral hyperemia from cerebral anemia.

8. Differentiate erysipelas from erythema. Give treatment of former.

EYE AND EAR.

1. What is phlyctenular conjunctivitis? Give treatment.

2. Name some of the ulcers of the cornea.

3. What are the symptoms of acute catarrh of the middle ear?

4. What are the symptoms of otitic mengitis?

NERVOUS DISEASES.

1. What are the phenomena of the reaction of degeneration?

2. What is the etiology and pathology of tabes dorsalis?

3. Give treatment of alcoholic multiple neuritis.

4. Give prominent symptoms of paralysis agitans.

DISEASES OF WOMEN.

1. Give in detail the operation for post-operative ventral hernia.

2. Give the diagnosis and treatment of intestinal adhesions following laparotomy.

3. Give early diagnostic symptoms of malignancy of the mammary gland.

4. Patient 54 years old, give symptoms of malignancy of the uterus.

5. Give causes and symptoms of vesicovaginal fistula.

6. Have the ovaries any influence upon catalepsy? State your reasons.

7. Following abdominal operation, what causes fecal fistula? What treatment is demanded?

8. Define leucorrhea and give three causes.

OBSTETRICS.

1. What is the conjugate and transverse diameter of the inlet and outlet of the pelvis? Give its anatomical points of measurement.

2. What is the cause of rupture of the uterus, and under what circumstances does it occur?

3. Give your treatment for inevitable abortion.

4. Give your treatment for post-partum hemorrhage.

5. Give cause and treatment for transverse presentations.

6. Give cause, diagnosis, and treatment for puerperal eclampsia.

7. When would you use forceps and how?

8. Give the anatomy of the uterus, and state what changes take place during gestation.

DISEASES OF CHILDREN.

1. Give diagnosis and treatment of spasmodic croup.

2. What are the causes of convulsions in infants and children?

3. What is the prognosis and treatment in diphtheria?

4. Give differential diagnosis of measles, scarlet fever, chicken-pox.

5. Give symptoms of acute bronchopneumonia.

6. Give prophylaxis and treatment of ophthalmia neonatorum.

7. Give a word picture of a case of scabies.

8. Give causes and treatment of summer diarrhea.

SURGERY.

1. Discuss angioma and its varieties.

2. What symptoms would make you suspect malignant disease of the sigmoid colon? Indicate treatment.

3. If called to a case of compound fracture of both bones of the leg four hours after the accident, what conditions would decide you for or against amputation?

4. Describe the early symptoms of caries of the dorsal spine, and diagnostic tests for this condition.

5. What are the causes of fistula *in ano?* Discuss the pathology of this condition.

6. Discuss the pathology of congenital torticollis, and its treatment.

7. Describe, step by step, the removal of the left half of a large simple goiter.

8. What are the causes and symptoms of acute suppurative osteomyelitis of the tibia?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF OREGON.

Portland, January 7, 8, and 9, 1908.

PHYSIOLOGY.

1. *Tidal air* is the air which is constantly passing in and out of the lungs during ordinary calm respiration. It measures about 30 cubic inches.

Complemental air is the air which can be taken in beyond what is normally inspired in ordinary breathing. It measures about 100 cubic inches.

Supplemental air is the air which can be expelled at an extraordinary expiration. It measures about 100 cubic inches.

Residual air is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

2. The *function of the carbohydrates* is to supply animal heat and energy; also to form fats and possibly to help form proteids.

3. *Tetanus* is the condition produced in a muscle when it is stimulated so rapidly that it has no time to relax between one stimulus and the next one; the result is a prolonged, steady contraction.

7. *Secreting membranes* are: (1) *Serous* membranes, as the pleuræ, pericardium, peritoneum, tunica vaginalis of the testis. (2) *Synovial* membranes, in the articulations. (3) *Mucous* membranes, lining the digestive, respiratory, and genitourinary tracts. (4) *Cutaneous* membrane, or skin.

8. "The waves of sound are gathered together by the pinna and external auditory meatus, and conveyed to the membrana tympani. This membrane, made tense or lax by the action of the tensor tympani and laxator tympani muscles, is enabled to receive sound waves of either high or low pitch. The vibrations are conducted across the middle ear by a chain of bones to the foramen ovale, and by the column of air of the tympanum to the foramen rotundum, which is closed by the second membrana tympani, the pressure of the air in the tympanum being regulated by the Eustachian tube. The internal ear finally receives the vibrations, which excite vibrations successively in the perilymph, the walls of the membranous labyrinth, the endolymph, and, lastly, the terminal filaments of the auditory nerve, by which they are conveyed to the brain." —(Brubaker's *Physiology.*)

ANATOMY.

2. The posterior triangle of the neck is bounded: *Anteriorly*, by the posterior border of the Sternomastoid; *posteriorly*, by the anterior border of the Trapezius, and *below* by the superior border of the clavicle. Its apex is at the occiput. It is subdivided into the occipital and subclavian triangles, by the posterior border of the Omohyoid.

The *floor* is formed by the Splenius capitis, Levator anguli scapulæ, and the Scalenus medius and posticus.

The *roof* is composed of: Skin, Platysma myoides, superficial and deep fascia.

The *contents* are: *Arteries*: Subclavian (third part), suprascapular, transversalis colli, occipital, and superficial cervical. *Veins*: Suprascapular, transversalis colli, external jugular, sometimes the subclavian. *Nerves*: Spinal accessory, branches of cervical plexus, brachial plexus. *Other structures*: Lymphatic glands and Scalenus anticus.

4. The principal branches of the Fifth Cranial Nerve are:

I. *Ophthalmic*, giving off the: Lacrymal, Frontal, and Nasal.

II. *Superior Maxillary*, giving off the: Meningeal, Orbital, Spheno-palatine, Posterior superior dental, Middle superior dental, Anterior superior dental, Infraorbital, Palpebral, Nasal, and Labial.

III. *Inferior Maxillary*, giving off the: Recurrent, Internal pterygoid, Masseteric, Deep temporal, Buccal, External pterygoid, Auriculo-temporal, Inferior dental, and Lingual.

5. The anatomical structures which lie beneath Poupart's ligament are (from without inward): External cutaneous nerve, Iliacus, anterior crural nerve, Psoas, femoral artery, femoral vein, femoral ring.

6. In amputation through the middle of the arm the following parts are divided: Skin; fascia; Biceps, Triceps, and Brachialis anticus muscles; brachial, superior profunda, and inferior profunda arteries; brachial, basilic, and cephalic veins; median, ulnar, internal cutaneous, musculo-spiral, and musculo-cutaneous nerves; and humerus.

8. The *blood supply of the eyeball*: The short posterior ciliary, long posterior ciliary, and anterior ciliary arteries, and the arteria centralis retinæ.

HISTOLOGY.

2. The principal forms of connective tissue are: White fibrous, yellow elastic, areolar, mucous, retiform, adipose, adenoid, neuroglia, cartilage, bone, dentine, and blood.

3. Course of the urine from the capsule of Bowman to the pelvis of the kidney: The neck of the capsule, proximal convoluted tubule, spiral tubule, descending limb of Henle's loop, Henle's loop, ascending limb of Henle's loop, zigzag tubule, distal convoluted tubule, junctional tubule, collecting tubule, duct of Bellini.

4. The corpuscular elements in the blood are: Red or colored corpuscles, white or colorless corpuscles, and platelets.

CHEMISTRY.

1. An *element* is a substance which cannot by any known means be split up into two or more other kinds of substance. There are, at present, eighty elements.

2. *Matter* is anything which occupies space. Example, a cannon ball.

Force is that which produces or tends to produce motion or change of motion in matter. Example, gravitation.

Energy is the capacity of matter for doing work. Example, falling water may turn a wheel.

3. *Chemical affinity* is the force that binds atoms together to form molecules.

It differs from other forces in: (1) Only acting between atoms, and not on molecules or masses; (2) being able to effect changes in chemical composition; (3) it will not act at a distance, but the atoms must be in intimate contact; (4) it will not act if other substances are interposed; (5) it is usually necessary to start or to support it by heat, or electricity, or other agency.

4. In examining *normal* urine the following points are to be considered:

The quantity voided in twenty-four hours, its general appearance, color, odor, reaction, specific gravity, quantity of solids excreted, quantity of urea, uric acid, chlorides, sulphates, phosphates.

In *abnormal* urine, in addition to the above, examination should be made for albumin, sugar, excess of indican, acetone, blood, bile, pus, casts, epithelium, parasites, pathogenic bacteria, and foreign bodies.

5. Test for *Bile*: Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool, When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

Test for *Blood*: To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

Chemical test for *Pus* in the urine: Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

A comparatively easy test for *Urea* is that of Fowler, based upon the loss of the specific gravity of the urine after the decomposition of the urea by hypochlorite. "To apply this method the specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ (Squibb's). One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7791 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely." (Witthaus' *Manual of Chemistry.*)

6. Tests for the detection of *Morphine*: (1) Add a solution of neutral ferric chlorid; a blue color is given in the presence of morphine. (2) Add some Fröhde's reagent (a fresh solution of ammonium molybdate in concentrated sulphuric acid); in the presence of morphine a violet color is produced, which changes to blue, dirty green, and pale pink.

7. Tests for *Arsenic*: Marsh's and Reinsch's are the two most commonly used tests. Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry, glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

8. To test for *Strychnine*: Add concentrated suphuric acid; it forms a colorless solution; a crystal of potassium bichromate, if drawn through this solution, produces a track of color, which is in turn blue, violet, rose-colored, and yellow.

MATERIA MEDICA AND THERAPEUTICS.

1. There are only two official digestive ferments, viz., pepsin and pancreatin. Ingluvin and papayin are also digestive ferments.

Pepsin is indicated as an aid to gastric digestion in gastralgia, gastric cancer and ulcer, atonic dyspepsia, and the vomiting of pregnancy.

Pancreatin is indicated as an aid to digestion, and for the predigestion of food, in convalescence, in wasting diseases, and in intestinal dyspepsia.

2. When mineral acids are taken into the stomach, they unite with bases and form neutral salts.

3. Phosphorus acts locally as an irritant: internally it is a stimulant to the nervous system and also to the bone-forming cells, a tonic, a repairer of waste, a circulatory stimulant and an aid to the formation of red blood corpuscles. It is partly oxidized into phosphorus acid or phosphoric acid, of the oxygen in the red corpuscles. In large doses it increases the urea and other nitrogenous products, raises the body temperature, diminishes the glycogen of the liver, and may cause fatty degeneration.

4. The official preparations of arsenic, with their doses, are: Arseni trioxidum, gr. 1/30; Liquor acidi arsenosi, ♏vij; Arseni iodidum, gr. 1/20; Sodii arsenas, gr. 1/6; Sodii arsenas exsiccatus, gr. 1/20; Liquor potassii arsenitis, ♏vij; Liquor sodii arsenatis, ♏v; Liquor arseni et hydrargyri iodidi, ♏vij.

5. Two stimulating expectorants: The ammonium salts and senega.

The chloride of ammonium is thus used in doses of gr. x-xx, in bronchorrhea and chronic bronchitis, and the carbonate of ammonium in doses of gr. v is used in the crisis of pneumonia.

Senega is used as an expectorant in chronic bronchitis, and in acute bronchitis; the dose of the syrup of senega is ʒi; of the fluid extract ♏xv.

7. *Therapeutic indication for digitalis*: Mitral lesions of the heart, cardiac palpitation, irritable heart from nerve exhaustion, cardiac and renal dropsy, exophthalmic goiter.

Therapeutic indications for amyl nitrite: Angina pectoris, epilepsy, whooping cough, asthma, laryngysmus stridulus, and high arterial tension in arteriosclerosis, nephritis.

8. Two motor depressants: Chloral and stramonium.

Chloral is indicated: As a hypnotic in insomnia, in whooping cough, tetanus, strychnine poisoning, hernia, convulsions.

Stramonium is indicated: In asthma, whooping cough, chorea, dysmenorrhea, neuralgia, mania.

DIAGNOSIS.

1. In Pott's fracture the foot is twisted outward, the sole everted, and the heel drawn up; there is a depression at the site of the fracture, the inner malleolus either projects prominently or the fragment can be felt and crepitus elicited; the foot is shortened, and the ankle is swollen and widened.

2. Gallstones in the gall-bladder may give no symptoms at all; or there may be dull pain localized over the region of the gall-bladder, digestive disturbances, muscular rigidity, and leucocytosis; or there may be very severe pain in

the region of the gall-bladder, radiating to the right shoulder and the epigastrium, with vomiting, collapse, severe sweating, and sometimes jaundice.

3. Stenosis of the pylorus is diagnosed by the peculiar recurrent vomiting of large quantities of food, some of which has been in the stomach for several days; the vomitus contains the *Sarcina ventriculi* and several bacteria; the stomach is prolapsed considerably; a splashing sound may be elicited on palpation, and sometimes a tumor may be felt in the region of the pylorus.

4. The shortening is caused by the action of the following muscles: The Glutei, Biceps, Semimembranosus, Semitendinosus, Tensor vaginæ femoris, Rectus, Sartorius, Adductors, Gracilis, and Iliopsoas.

5. Abscess of the liver is diagnosed by: The enlargement of the liver, jaundice, tenderness, pain which may radiate to the right shoulder; emaciation, chills, fever, and sweats may also be present; aspiration will confirm the diagnosis by revealing pus; there may also be leucocytosis and anemia.

6. In *scarlet fever* the eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat.

In *measles* the eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present.

7. In green-stick fracture of the radius in a child two years old a bowing or angle in the bone may be detected on palpation, there will usually be a history of a fall on the outstretched hand or on the forearm, pain and tenderness with "favoring" of the part will be apparent, and an *x*-ray examination may clear up the diagnosis.

8. The *symptoms of stone in the male bladder* are: Increased frequency of micturition; pain at end of urination, chiefly felt at the end of the penis or in the neck of the bladder; the urine may contain pus, mucus or blood; a "click" can be obtained by using a searcher or sound; examination by the cystoscope may reveal the presence of the stone.

PRACTICE OF MEDICINE.

4. In *asthma* the dyspnea is expiratory only: In *edema of the glottis* it is inspiratory, and occasionally expiratory also.

5. Syphilitic ulcers of the pharynx and tubercular ulcers of the pharynx are differentiated by Bosworth as follows:

SYPHILITIC ULCERS.	TUBERCULOUS ULCERS.
Deeply excavated.	No apparent excavation.
Few granulations, and those highly inflammatory.	Much indolent granulation.
Deep-red areola.	Faint areola.
Sharply-cut edges.	Irregular and ill-defined edges.
Distinct demarcation.	Demarcation indistinct.
Yellow purulent secretion.	Grayish, ropy mucous secretion.
Discharge profuse.	Discharge scanty.
Penetrating to deeper tissues.	Superficial, with lateral in place of deep extension.
No fever as a rule.	Hectic fever as a rule.

7. *Cerebral hyperemia* is characterized by: Fullness in the head, vertigo, restlessness, insomnia or disturbed sleep, ringing in the ears, and forgetfulness; on lying down the symptoms become worse; hyperemia of the retina may be detected by the ophthalmoscope.

Cerebral anemia is characterized by: Pallor, nausea, vertigo, yawning, dilated pupil, headache, forgetfulness, tinnitus aurium, and forgetfulness; on lying down the symptoms improve; pallor of the retina may be detected by the ophthalmoscope.

8. *Erysipelas* is characterized by: A rise of temperature; a tendency to spread; the skin is swollen and the affected part has a well-defined border and raised margins; there are pain, considerable constitutional disturbance, and a possibility of infection.

In *erythema*: There is no rise of temperature, no tendency to spread, no raised margins, no constitutional disturbance; the margin of the rash gradually fades into skin of a normal healthy color.

EYE AND EAR.

2. *Some of the ulcers of the cornea*: Catarrhal, creeping, deep, infected, rodent, simple, superficial, dendritic, indolent.

NERVOUS DISEASES.

1. *The phenomena of the reaction of degeneration*: "In health a sharp contraction occurs if a faradic current is applied to a nerve or over a muscle, and a similar contraction can be obtained with the galvanic current just when the circuit is closed or broken, but not when the current is passing.

"In contrast with these conditions is the *reaction of degeneration*. When this is present we obtain no muscular twitching with the faradic current and none over the nerve with the galvanic; but *with the galvanic over the muscle a slow, worm-like contraction* occurs, and the response to the positive pole is as good as to the negative, or better; whereas, normally there is far better response to the negative. This is the *complete* reaction of degeneration; in *partial* reactions of degeneration all the normal reactions may be present, but diminished in intensity." (Cabot's *Physical Diagnosis.*)

2. TABES DORSALIS: *Etiology*: Tabes dorsalis is a disease of adult life; is more common in men than in women; is more common in cities than in the country; syphilis is believed to be the most frequent direct cause; alcoholism, injury, exposure to cold and wet, have all been urged as causes, but they are not now assigned so important a place as etiological factors as was formerly the case.

Pathology: Tabes dorsalis is a condition in which the posterior columns and nerve roots of the spinal cord are degenerated, and which is characterized by incoordination, loss of deep reflexes, and various disturbances of sensation and nutrition.

The posterior columns of the cord are gray and shrunken and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

4. *The prominent symptoms of paralysis agitans* are: A fine tremor, usually beginning in the hand; muscular rigidity, with the head bowed, the body inclined forward, and the knees bent; the "festinating gait," in which the patient walks faster and faster and even runs, to avoid falling forward; the face is expressionless.

DISEASES OF WOMEN.

3. The *early diagnostic symptoms of malignancy of the mammary gland* are: An ill-defined thickening of one of the lobes of the breast, or a nodular swelling; generally painless, or accompanied by an occasional darting pain; it is an indolent swelling, with no signs of inflammation, and perhaps an induration of the part; an exploratory puncture or incision will settle the diagnosis between malignancy and a cyst.

4. In a patient 54 years old the symptoms of malignancy of the uterus would be: Hemorrhage, an offensive discharge, and pain; later on, chachexia.

5. *Vesicovaginal fistula may be caused* by: Injuries, and traumatisms received during labor; ulceration due to a retained or ill-fitting pessary, or a vesical calculus; a malignant growth of the bladder or vagina.

Symptoms: The urine constantly dribbles from the vagina; micturition is painful; excoriation of vagina, vulva, and thighs; cystitis may be present, and the patient's general health deteriorates.

7. *Fecal fistula following abdominal operation may be caused* by: Injury to the intestine while separating adhesions; leakage of the intestine after an anastomosis or suturing; necrosis of the intestine from pressure or from an inflammatory mass.

The treatment demanded is: Cleanliness; protection from irritation, and, failing ultimate healing, operative treatment is required.

8. *Leucorrhea* is a whitish discharge from the uterus or vagina.

Three causes: Pelvic congestion, endometritis, retroversion of the uterus.

OBSTETRICS.

1. The *conjugate diameter* of the *inlet* of the pelvis is a line drawn from the middle of the sacral promontory to the top of the symphysis pubis. It is about four inches in length.

The *transverse diameter* of the *inlet* of the pelvis is a line drawn right across the pelvis from one lateral margin of the brim to the other. It is about five inches in length.

The *conjugate diameter* of the *outlet* of the pelvis is a line drawn from the tip of the coccyx to the lower surface of the symphysis pubis. It is about five inches in length.

The *transverse diameter* of the *outlet* of the pelvis is a line extending across the pelvis from one tuberosity of the ischium to the other. It is about four inches in length.

2. The cause of *rupture of the uterus* is: Strong uter-

ine contraction in combination with some obstacle to the birth of the fetus. It is apt to occur in cases of contracted or deformed pelves, transverse presentation, obstruction from tumors, unduly large fetal head.

3. In *inevitable abortion* there are two lines of treatment:

(1) The *expectant,* which consists in absolute rest, the insertion of tampons in the vagina, vaginal douches, and the administration of ergot.

(2) *Active treatment,* which consists in anesthetizing the patient, dilating the os, and removal of the products of conception generally by curettage. This is followed by intrauterine douche and sometimes by the application of Churchill's tincture of iodine to the uterine cavity, and insertion of gauze.

7. *Indications for the use of forceps* are: "1. *Forces at fault*: Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault*: Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault*: A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications*: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both." (From Jewett's *Practice of Obstetrics.*)

DISEASES OF CHILDREN.

2. *Causes of convulsions in infants and children* are: "Overeating, especially of indigestible food; rachitis, debility from exhausting diarrheal diseases; high fever, especially at the onset of the acute specific infections; very seldom dentition, phimosis, and acute middle-ear inflammation; injuries to the brain at birth, infantile hemiplegia, meningitis, and tumor of the brain; rarely of spinal cord disease." (From Butler's *Diagnostics of Internal Medicine.*)

6. *Prophylaxis of ophthalmia neonatorum*: Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth.

Treatment: Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

7. *Scabies* is a contagious, animal, parasitic disease due to the *Sarcoptes scabiei,* characterized by burrows and a multiform eruption, and attended by severe itching. The eruption usually occupies certain areas where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the mammæ and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes. The face is exempt except occasionally in infants. The itching is intense and worse at night. The affection is curable, but dermatitis may result from overtreatment.

SURGERY.

3. If the blood-vessels are injured to such an extent that it is evident that the foot must become gangrenous, or if the large arteries are divided, amputation should be performed. So, too, when there is much destruction of bone, and when there is much suppuration and indications of septicemia. If it is probable that recovery will be long and tedious and in the end the patient will only have a limb of doubtful value, the patient should be asked to decide the question of amputation.

4. The *early symptoms of caries of the dorsal spine* are: (1) The child easily tires, even in his play, and often wants to lie down and rest; (2) local tenderness, which is found by pressing over the spinous processes one at a time, and also by pressing lightly on the head; (3) all movements are made very carefully, from fear of causing pain; (4) in picking up anything from the floor, the child will keep the spine rigid and bend the knees; (5) the shoulders are apt to be elevated and the spine kept rigid.

5. The *causes of fistula in ano* are: Some suppurative condition in the neighborhood of the rectum, such as an anal abscess or ischiorectal abscess; stricture of the rectum; perforation of the mucous membrane of the rectum by some foreign body, such as a fish-bone, and ulceration of the mucous membrane of the rectum.

Pathology: There are four varieties: (1) The *complete,* which opens into the rectum internally and on the perineum externally; (2) the *external incomplete,* or *blind external,* which opens on the perineum but not into the rectum; (3) the *internal incomplete* or *blind internal,* which opens into the rectum but not on the perineum; (4) the *horseshoe* fistula, which extends around the rectum and opens on each side. The internal opening is generally between the two sphincters, but may be above the internal sphincter and below the external sphincter. There may be several pockets or side tracts extending in different directions.

6. *Pathology of congenital torticollis*: "In the ordinary type of congenital torticollis, as demonstrated at operations on children, the substance of the affected muscle or muscles is simply lessened in amount, and there is a disproportionate area of tendinous substance, as contrasted with the contractile tissue. In other instances the muscle may be traversed by fibrous bands or patches of scar-like tissue. Such changes are far more common in acquired torticollis, and they indicate primary or secondary inflammation of the muscular substance. In cases of torticollis in infancy, or when the distortion is slight, there is but little general effect of the local contraction; but, if the deformity persists, secondary changes appear. The face on the affected side is flatter, the nose, the corner of the mouth, and the eyelids may be drawn down toward the contraction, and the skull even may be markedly deformed. There is in all cases of this character lateral distortion of the cervical spine, the convexity being on the side opposite the contraction. Later, secondary curvature of the spine develops. Usually there are also an increase of the dorsal convexity, "round shoulders," and a lateral compensatory curve in the direction opposed to the superior deformity. If the deformity persists the neighboring muscles become eventually involved, together with the other tissues on the contracted side, the fascia presenting the greatest resistance to the correction." (*Reference Handbook of the Medical Sciences.*)

BULLETIN OF APPROACHING EXAMINATIONS †

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery		
Arizona*	Ancil Martin, Phoenix	Phoenix	April	6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April	7
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	7
Connecticut*	Chas. A Tuttle, New Haven	New Haven	July	14
Delaware	J. H Wilson, Dover	Dover	June	16
Dist. of Col'bia	W. C. Woodward, Washington	Washington	April	14
Florida*	J. D. Fernandez, Jacksonville	Ocala	April	13

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MORTMAIN. By ARTHUR TRAIN. 12mo, 314 pages, cloth, illustrated. D. Appleton & Company.

TRANSACTIONS OF THE FIFTH ANNUAL CONFERENCE OF STATE AND TERRITORIAL HEALTH OFFICERS WITH THE UNITED HEALTH AND MARINE HOSPITAL SERVICE. 8vo, 47 pages, cloth. Government Printing Office, Washington.

TEXT-BOOK OF OPHTHALMOLOGY. By Dr. ERNEST FUCHS. Large 8vo, 908 pages, illustrated, half morocco. J. B. Lippincott Co., Philadelphia.

DISEASES OF THE BREAST, WITH SPECIAL REFERENCE TO CANCER. Large 8vo, 385 pages, illustrated, half morocco, $4 net. P. Blakiston's Son & Co., Philadelphia.

PRACTICE OF MEDICINE FOR NURSES. By GEORGE HOWARD HOXIE, A.M., M.D. 8vo, 284 pages, illustrated, muslin $1.50 net. W. B. Saunders Company, Philadelphia.

HEALTHY BOYHOOD. By ARTHUR TREWBY, M.A. 16mo, 63 pages, muslin, 40c. net. Longmans, Green & Co., New York.

MEDIZINAL-BERICHTE ÜBER DIE DEUTSCHEN SCHUTZGEBIETE, 1905-06. 8vo, 440 pages, cloth 50 Fr. Ernst Siegfried Mittler und Sohn, Berlin.

TRAITÉ PRATIQUE DE THÉRAPEUTIQUE INFANTILE. Par les Drs. PAUL LE GENDRE and AUG. BROCA. Large 8vo, 759 pages, illustrated, muslin, 15 francs. G. Steinheil, editeur, Paris.

HEMATOLOGICAL ATLAS. By Priv. Doz. Dr. KARL SCHLEIP. 4to, 257 pages, illustrated, half leather, $10. Rebman Company, New York.

THE PRODUCTION AND HANDLING OF MILK. By KENELM WINSLOW, M.D., M.D.V., B.A.S. (Harvard). Large 8vo, 207 pages, illustrated, muslin. William R. Jenkins Co., New York.

DETECTION OF THE COMMON FOOD ADULTERANTS. By EDWIN M. BRUCE. 12mo, 84 pages, muslin. D. Van Nostrand Company, New York.

TRANSACTIONS OF THE LUZERNE COUNTY, PA., MEDICAL SOCIETY, for the Year Ending December 31, 1907. Vol. XV. The E. B. Yardy Co., Wilkes-Barre, Pa.

REPORT OF THE COMMISSIONER OF EDUCATION, for the Year Ending June 30, 1906. Vol. 2. Government Printing Office, Washington, 1908.

CONFESSIO MEDICI. By author of "The Young People." 12mo, 158 pages, muslin, $1.50 net. The Macmillan Company, New York.

HYPNOTIC THERAPEUTICS IN THEORY AND PRACTICE. By JOHN DUNCAN QUACKENBOS, A.M., M.D. 8vo, muslin, 332 pages, $2 net. Harper & Brothers, New York.

VERHANDLUNGEN DER DEUTSCHEN LARYNGOLOGISCHEN GESELLSCHAFT AUF DER II. VERSAMLUNG. Von Dr. Med. GEORG AVELLIS. Large 8vo, 176 pages, paper, 5 marks. A. Stuber's Verlag (Curt Kabitsch), Würtsburg.

LES LUXATIONS DES GRANDES ARTICULATIONS, LEUR TRAITEMENT PRATIQUE. Par les Drs. J. HENNEQUIN et ROBERT LOEWY. Large 8vo, 407 pages, illustrated, paper, 16 francs. Felix Alcan, Editeur, Paris.

THE BLIND-DEAF. By WILLIAM WADE. 4to, 149 pages, paper, illustrated. Hecker Bros., Indianapolis.

PROCEEDINGS OF THE ROYAL SOCIETY OF MEDICINE. Edited by JOHN NACHBAR, M.A., M.D. Large 8vo, illustrated, paper, 7 shillings 6 pence. Longmans, Green & Co., New York.

REPORT—BIRTHS, MARRIAGES AND DEATHS, ONTARIO, 1905. Large 8vo, muslin. L. K. Cameron, Toronto.

TWENTY-FIRST ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF THE STATE OF OHIO. Large 8vo, 552 pages, paper. F. J. Heer, State Printer, Columbus.

DISEASES OF THE NOSE AND THROAT. By HERBERT TILLEY, B.S. (Lond.), F.R.C.S. (Eng.). 8vo, 539 pages, illustrated, muslin, 14s. net. H. K. Lewis, London.

VITALITY, FASTING AND NUTRITION. By HEREWARD CARRINGTON. Large 8vo, 648 pages, illustrated, muslin. Rebman Company, New York.

DIE FEHLERGROSSE BEI DEN HISTOLOGISCHEN METHODEN. By Dr. Med. W. BERG. Large 8vo, 48 pages, paper, 1 mark 20 phg. Verlag von August Hirschwald, Berlin.

ILLUSTRATED CATALOG OF ELECTRO-THERAPEUTICAL APPARATUS. 8vo, 159 pages, paper, illustrated. McIntosh Battery & Optical Company, Chicago.

A MANUAL OF PRESCRIBING. By C. R. MARSHALL, M.D. 16mo, 373 pages, muslin, $2 net. J. & A. Churchill, London.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 21, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	507	168
Diphtheria	397	53
Measles	1607	33
Scarlet Fever	961	37
Smallpox	—	—
Varicella	218	—
Typhoid Fever	27	4
Whooping Cough	21	3
Cerebrospinal Meningitis	10	9
Malarial Fever	—	—
Totals	3748	307

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending March 20, 1908:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.
Alabama, Mobile	Feb.	1–8	6	..
"	Feb.	22–29	5	..

THE DEEP INTRAOCULAR LESIONS OF INFANTILE INHERITED SYPHILIS AND TARDY INHERITED SYPHILIS, FROM THE STANDPOINT OF GENERAL PATHOLOGY, PROGNOSIS, AND TREATMENT.*

By CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

My object in presenting this paper is to make an urgent appeal for the early and more careful examination of the eyes of infants and young children, where syphilis is suspected or known to exist in the parents or family. The examination should begin with the newborn infant, and, where possible, should be repeated at intervals until the infant has reached adult life. The object of beginning the investigation with the newborn infant is to determine, if possible, what proportion of these cases of intraocular disease are fetal in origin, as distinguished from those developed in infancy and childhood, and especially from the cases of tardy development of the disease in youth or middle age. My own experience has convinced me that the cases of intrauterine disease of the deeper tissues of the eye are far more common than is usually supposed. As a natural corollary to this proposition, it follows that the earlier the existence of such disease is recognized, its cause known, and proper treatment instituted, the better the prognosis as to the ultimate vision.

The statement that cases of congenital syphilis of the eyes are usually comparatively mild, must in the light of my own experience be rejected; for, while it is true that many of the cases die *in utero* or shortly after birth, many of the so-called "bad cases" live through infancy and early childhood, but with extremely marked intraocular stigmata; for intrauterine infection runs its destructive course much more rapidly than where the infection develops after birth.

Lesions of the deep structures of the eye are by no means infrequently actually *congenital*, as iritis, cyclitis, chorioiditis, cataract, exudation in the vitreous, and, more rarely, retinitis, optic neuritis, and atrophy of the optic nerve have been observed in infants within a few hours after birth. Here the destructive inflammation must have begun *in utero*.

From my own observation I am inclined to believe that disease of the uveal tract, especially iritis and chorioiditis, is more frequently met with in young infants than keratitis, as an evidence of inherited syphilis. While the iritis may occur alone, it is more likely to be associated with cyclitis or chorioiditis, and its recognition is sometimes difficult owing to the presence of keratitis with corneal opacity, or to the symptoms being but slightly marked, or because of the absence of other well-marked stigmata. More frequently we meet with a chorioiditis disseminata associated with the iritis, and so close is this association that an ophthalmoscopic examination should always be made, where the field of the pupil is not blocked by exudation. This condition has been seen by me a number of times in infants at birth, where a careful examination has been made of the baby's eyes, and is literally congenital, due to intrauterine inflammation of one or both eyes. These infants are always very badly nourished, and are not infrequently stillborn.

The *iritis* is of the plastic type, and I have myself never met with gummata of the iris in an infant. Iritis due to inherited syphilis in infants and very young children was first described by Lawrence in 1830, and the usual period for its development has been placed during the fifth month of life, but cases do occur at a much earlier period. Some of the symptoms, like the ciliary injection and the exudation, are often but slightly marked, or partially concealed by an interstitial keratitis. It may be unilateral or bilateral, and is particularly liable to relapses. The prognosis varies with the occurrence of other ocular stigmata, and is more favorable if there be no keratitis or chorioiditis. It also depends greatly on the stage or period at which these infants come under proper treatment. As influencing the prognosis, it may be stated that iritis in infants and young children, due to inherited syphilis, rarely occurs alone, but almost always with chorioiditis. The prognosis is also influenced by the fact of both parents being syphilitic, for it is generally admitted that the degree of severity with which an infant suffers from inherited syphilis is usually in proportion to the length of the period which has elapsed since the parents contracted the disease.

Among the deeper structures of the eye, the chorioid is most likely to be affected in infants and young children, and, owing to the fact that at this age interstitial keratitis is very rare, the chorioiditis may be the more readily recognized, *but it must be looked for*. It may be traced through several distinct stages, beginning with small round or oval patches in the stage of efflorescence, followed by general retinal edema and vitreous opacities, later by accumulations of pigment, and ending in clearly outlined patches of atrophy surrounded by pigmented margins and free from retinal edema. These changes chiefly involve the chorioid, though the retina also suffers; but the ultimate visual acuity is so good, even after a most extensive chorioiditis, that the retina could have been only slightly affected.

This condition of the chorioid, like the iritis, is not very uncommon at birth, and cases have been reported in which the condition was recognized either at birth or so shortly afterwards as to prove that the disease preceded the birth and began *in utero*. In young children who are old enough to have their vision tested, the disproportion existing between the

*Read by invitation before the Baltimore City Medical Society, February 21, 1908.

actual condition of the chorioid and the real visual acuity is a very striking feature. The chorioid may be riddled with the disease from periphery to center, while the central vision may be but little affected. Sometimes the vision suddenly fails without the ophthalmoscope showing any fresh evidences of disease, but this loss of vision is temporary and is rapidly followed by a restoration almost to the normal standard. The probability is that in these cases occurring in infants, the retina does not suffer except in the hexagonal pigment cell layer, which separates it from the underlying chorioid.

Turning from the uveal tract we consider next the *retina* and *optic nerve*. There being no external visible signs of retinitis or optic neuritis, syphilitic lesions of these tissues can only be recognized when special search is made for them. In newly born infants I have never seen a case of retinitis or optic neuritis in the stage of efflorescence; but in three infants, whom I examined within an hour after birth, besides the existing iritis, I found a neuroretinitis in the atrophic stage, with contracted arteries and a pale optic disc.

The *retinitis* due to inherited syphilis in infants and young children often leads to permanent changes in the retina, which vary from mere faint lines along the smaller peripheral arterial branches to complete obliteration of the vessels, so that both ophthalmoscopically and microscopically they appear as white cords.

Optic neuritis is found occasionally in infants and young children, either alone or at times associated with chorioiditis. The optic disc is seen to be red, with blurred outlines, but there is little or no edematous swelling, such as we see in papillitis. Such cases as I have been able to follow for a length of time ended in partial or complete atrophy of the optic nerve.

From my own experience, therefore, I conclude that it is not a very uncommon thing for syphilitic infants to be born with already well-marked symptoms of disease of the uveal tract. This is an additional proof, if any were needed, that the fetus *in utero* may suffer from inherited syphilis, and yet be born at full term and live. Most of these infants are said to be free from symptoms of syphilis at the actual birth, but these symptoms soon appear, often within the first week of life; and as regards the internal lesions of the eye, I believe their apparent rarity is because they have not been looked for and because the external symptoms are sometimes so slightly marked. For instance, I have seen cases of iritis with little or no ciliary injection, and with only slight swelling and discoloration of the iris tissue; yet, on close investigation, adhesions were found to exist and some cloudiness of the aqueous humor. In these very young infants I have noticed that the skin about the eyelids, forehead, and nose was thicker and more opaque than elsewhere on the body.

I have seen many cases of iritis and chorioiditis in infants and young children, and quite a number of cases of iritis at birth, actually congenital, and of intrauterine origin. I will mention briefly a few of these cases.

Infantile Inherited Syphilis.

Case I.—I was called many years ago to see a male infant only a few hours old, because it was feared the child had a purulent conjunctivitis. I found a slight mucous secretion, but no pus. There was both conjunctival and ciliary injection. The cornea was clear in both eyes. The iris was discolored, swollen and adherent to the lens capsule in both eyes, and in one eye there was an exudation in the field of the pupil. The child had mucous patches around the genitals and anus. I succeeded in partially dilating the pupils with a weak solution of atropine, and found the fundus normal. The baby was born at full term and was fairly well developed, but the face showed the marks of senility. He was immediately put on systematic treatment, as was the mother, but the iritis proved very obstinate, as I was not able to break all the adhesions. This child died during the first year of life of some abdominal trouble. Both parents showed unmistakable syphilitic lesions, and the mother had had two miscarriages.

Case II.—I was called to see a female child two days old, because it was thought she was blind. I found the conjunctiva and cornea perfectly healthy and there was no ciliary injection. Both eyes showed iritis with adhesions of the iris to the lens. After using atropine as frequently as I dared, I succeeded in breaking all the adhesions and dilating the pupils *ad maximum*. The opthalmoscope then showed a chorioiditis in both eyes, involving the periphery only, with floating opacities in the vitreous. This child also showed mucous patches around the genitals and a marasmic appearance, but lived to be nearly two years old, and had evidently fairly useful vision.

Case III.—I saw an infant ten hours old, last year, with well marked iritis in both eyes. The child was so weak that it was deemed unwise to attempt any local treatment. Both pupils were blocked by exudation, yet the ciliary injection was but slightly marked. The child lived only a few days.

Case IV.—Last autumn I was asked to see in consultation a female child, about six years old. I found the patient well developed for her age, but very excitable. I could not discover that anything unusual had been noted in the patient at birth. At times during the first year there had appeared a transient convergent strabismus of one or the other eye. It was noticed that the child always held everything very close to the eyes when looking at it. As she grew older, the strabismus became fixed in the left eye. At no time had there been any visible sign of inflammation in the eyes. When I examined the child I found the lids, conjunctiva, cornea, and iris and pupils normal. There was a convergent squint in the left eye, but no limitation of mobility in any direction. The media were clear. In both eyes the ophthalmoscope showed a very extensive chorioiditis pigmentosa in an advanced atrophic stage, and the optic discs were white. Vision was only 10/200. The child carried her head bent toward the left shoulder, but with the face rotated towards the right. The prognosis was, of course, most unfavorable, and no improvement could be expected from any treatment. The family history was markedly syphilitic.

Case V.—Another case of inherited syphilis in a very young female child I saw in consultation last November. The child was three years old, well developed mentally and physically, born at full term, but with mucous patches around the genitals and anus. Two days after birth she developed a purulent conjunctivitis of a mild type, from which she recovered in three weeks, without any corneal complication. About a week before I saw her both eyes became inflamed and there was marked photophobia. I found a double iritis with adhesions, the ciliary vessels injected, and evidently defective vision. After using a mydriatic, the adhesions of

the iris were broken, and the ophthalmoscope showed a recent chorioiditis in both eyes in the equatorial region. An older sister, aged twelve, showed the Hutchinson teeth and the remains of an interstitial keratitis. Both parents were syphilitic, and the mother was under treatment for a cutaneous lesion. Prompt treatment apparently checked the disease in the child.

When we come to consider the second division of our subject, the *Intraocular Lesions* of *Late* or *Tardy Inherited Syphilis,* the subject becomes more complex and the diagnosis more difficult. Fournier has made some interesting contributions to the study of such cases from time to time, and his last work, "L'Hérédo-Syphilis Tardive," just published, is said to be a monument of close and accurate observation.

It is probable that of all inherited morbid tendencies, the inherited syphilitic taint is met with the most frequently in all classes of life, and its stigmata are most variable in number and kind. A patient may show many stigmata in different parts of the body, or he may present but a single well-marked stigma, after the most rigid examination, as for instance the crescentically notched incisor teeth of Hutchinson. Again it may happen, after the most exhaustive and careful examination, that not a single stigma is found, which can be regarded as positively due to inherited syphilis, though the patient may be nearly blind from an optic neuritis or atrophy, which cannot be traced to any other morbid condition. This type of inherited syphilis is by no means rare. Experience would seem to prove that the most frequent stigmata of tardy inherited syphilis are those of the eye, and next in frequency are those of the teeth; and in a family of syphilities in which there are several children, there is often a very marked difference in the extent and number of the stigmata.

The etiology in these cases of *tardy* inherited syphilis is so obscure that the diagnosis becomes very difficult, and one of the difficulties against which we must contend is the predisposition to refer all these obscure cases to inherited syphilis as a cause. Hence arises the necessity for the most careful and searching investigation, not only of the patient, but of other members of the immediate family and the collateral relatives. Some assistance is occasionally gained from the patient's memory in regard to eye troubles in early childhood. The patient may remember having suffered from some disease of the eye in childhood, which lasted for weeks or months, and was accompanied by partial blindness. This would point to some grave lesion like interstitial keratitis or iridochorioiditis. A very careful examination of the eyes will then show the remains of stigmata, such as permanent deformity in the shape of the pupil, with the faint remains of posterior synechiæ, or a slight membranous deposit in the field of the pupil. If the cornea, iris, and pupil appear normal, the ophthalmoscope may reveal stigmata of the first importance as signs of inherited syphilis, which may be propagated to the third generation. These stigmata in the fundus oculi may appear either as gross lesions in the chorioid, retina, or optic nerve, which are immediately regarded as pathognomonic of inherited syphilis, or merely as slight rudimentary signs of former lesions.

The gross lesions of the fundus appear as atrophic patches of chorioretinitis, or as mere pigmentary deposits. The atrophic patches are irregularly round or oval, of varying size, and generally of a dense white color. The pigmentary deposits appear as dense black patches of varying size and shape all over the fundus, sometimes with a white center, which strongly resemble the spots of *leukomelanoderma* in the skin of syphilitic patients. If the chorioretinitis has occurred in the vicinity of the optic nerve, the stigma will appear as an irregular black border around the optic nerve entrance.

The rudimentary lesions are more frequently to be found in these suspected patients than the gross lesions. One of the most frequent is a lead-colored or slate-colored tint to the retina, spread more or less over the whole fundus, and most marked around the posterior pole. In some cases the pathological tint appears as small, lead-colored spots all over the fundus, giving a stippled appearance to the background, and most marked in the equatorial and ciliary regions, and hence more difficult of recognition.

A still more marked and characteristic rudimentary stigma is the arrangement of the pigmentary deposits in the form of the so-called "osteoplasts," with numerous processes or prolongations, usually found in the equatorial region, and to which we give the name of retinitis pigmentosa.

All these rudimentary stigmata are bilateral and to about the same extent in both eyes, and in my experience are the most common and significant evidences of inherited syphilis; or, to speak more accurately, while they are not by themselves positive proof of the existence of inherited syphilis, they must be regarded as strong presumptive evidence of the inherited taint.

In addition to the gross lesions and rudimentary stigmata shown by the ophthalmoscope in these cases, the retinal vessels, both arteries and veins, are reduced in caliber by thickening of the middle and inner coats, and this condition of the vascular walls is most marked in the retinitis pigmentosa. Associated with this condition is a partial atrophy of the optic disc, which may be mapped out as a defect in the visual field, sometimes central, sometimes paracentral in position; and here an additional stigma is found in a more or less marked mydriasis, which may vary in degree in the two eyes. Any one or all of these various stigmata may be found in the same patient, but they must be carefully looked for, as they are often so slight as to escape any but the closest scrutiny.

In most of these cases of *tardy inherited syphilis* there are certain functional ocular troubles, which are closely connected with the ophthalmoscopic stigmata just described. There is a congenital defective vision or *amblyopia,* due to a partial atrophy of the optic nerve, or to an optic neuritis occurring *in utero* or in early infancy, without showing any ophthalmoscopic evidence of its existence, until later in life.

Another functional symptom is *hemeralopia* or defective vision by night or in dimly lighted places, commonly known as *night-blindness.* This is a marked symptom in *retinitis pigmentosa* and is the direct result of the degenerative vascular and pigmentary changes in the retina. It is often a marked symptom in the amblyopia without ophthalmoscopic evidence, and is not infrequently seen in connection with the congenital cataracts of young children, where the opacity of the lens prevents examination of the fundus oculi. In several markedly syphilitic families which I have had an opportunity to examine, this has been a marked symptom in one or more of the children, even without the presence of *retinitis pigmentosa.*

Another functional stigma is *nystagmus,* both lateral and rotary, and in all such cases there is a marked bilateral amblyopia, due to pigmentary and

vascular degeneration in the retina, or to well-marked chorioretinitis.

Still another functional condition met with in tardy inherited syphilis is an *apparent myopia,* due to changes in the refractive power of the media, cornea, lens, or vitreous humor. These are cases of apparent change in the refraction of the eye, and not to any increase in length of the antero-posterior axis of the eye.

In addition to the gross lesions seen in the retina, the chorioid and the optic nerve, and to the more or less rudimentary stigmata seen in the iris, lens, and vitreous humor, I have observed certain malformations or evidences of defective development in the eyeball, which I am satisfied can be directly traced to inherited syphilis, and due to a fetal or intrauterine pathological process, such as microphthalmos and that form of congenital cataract known as zonular cataract. The latter is not infrequently seen in connection with retinitis pigmentosa and chorioretinitis, the presence of the latter being immediately recognized when the pupil is dilated by a mydriatic.

These patients with the stigmata of late inherited syphilis do not often present what is considered the classical type of the disease, as do almost invariably the infants and young children. They are not often undersized or of slender build, and rarely present a shriveled or stunted appearance. They do not show a badly-shaped head whether of the microcephalic or hydrocephalic type, though they often have a protuberant forehead, and some asymmetry in the development of the bones of the face, though not to the extent of any infantile physiognomy.

In most of the cases the diagnosis cannot be made with certainty until after the most searching scrutiny of the patient, and painstaking and extensive examination of the family. In the examination of the patient the ocular, dental, and aural stigmata are of the greatest value. Of these three groups, the dental stigmata are the most important, but the so-called Hutchinson teeth are not always well-marked. We do not always find the three distinct features of a crescentic notch in the cutting edge of the incisor teeth, the oblique convergent direction of these teeth, and the screw-driver shape. But besides these three distinctive features, there is often an erosion of the cusps of the first molar, and a vicious implantation of the teeth, associated with precocious caries and the absence of certain teeth; all of which assist the diagnosis. These dental stigmata are much more frequently present in the patients with late inherited syphilis than are the deep intraocular lesions, and yet sometimes they are so faintly marked as scarcely to excite a suspicion.

The diagnosis becomes relatively easy where the inherited taint has stamped itself on the general physiognomy of the patient. These may be a general stunted appearance, signs of senile decrepitude or a general infantile appearance from arrest of development. But there is nothing constant or regular in the occurrence of these stigmata. The facial stigmata are more often absent, or are so slightly marked as to escape all but the most careful observation. This is especially true of the flattening or lack of development of the bridge of the nose.

Certain aural stigmata are of value as diagnostic aids. If the patient has presented a history of severe acute deafness, coming on suddenly without any warning, and an examination reveals the absence of lesions which might account for it, there is great probability of the cause being inherited syphilis, which is increased if marked resistance to specific treatment is shown. Our recognition of the cause will be helped by remembering that while the inherited taint may affect the entire organism, it may also show itself in but a single organ, like the eye, the ear, or the teeth.

When, after the most rigid examination of the patient, no positive evidence is gained of inherited syphilis, we must turn to the family, both the immediate and collateral relatives, for assistance, and here the investigation must be made as rigid and extensive as possible. I believe that inherited syphilis may be transmitted through two or more generations, and this necessarily complicates the search.

The examination of the other children of the same family may reveal other stigmata present in the surviving children, and here the diagnostic indications are of value, because they often reveal the order in which the specific lesions have occurred.

Repeated miscarriages on the part of the mother and early infant mortality point almost unmistakably to inherited syphilis. Confinement before term of still-born infants, as well as confinement at full-term of still-born infants, are both strongly suggestive of syphilitic taint, and the same can be said of the death of infants during the first weeks of life, especially if the death occurs suddenly and without any apparent cause.

The Value of Symptoms.—In studying carefully any series of cases of disease we should try to understand the real significance of the symptoms presented as aids to a diagnosis. Hence we should try to estimate the real value of the stigmata in our diagnosis of inherited syphilis. There can be no just doubt in our minds that the presence of inherited syphilis is proved by the existence of several of the before-mentioned stigmata. I will go further and state that I believe the presence of only one stigma, even but faintly developed, points to the correct diagnosis of inherited syphilis, provided the examination of other members of the family reveals the presence of other stigmata.

It is even possible that a subject of inherited syphilis may not show a single stigma of the disease, though it may be proved to exist in the family for two or more generations, for it is generally admitted that in a syphilitic family there is often observed the greatest disparity in the development of the symptoms in different members of the family.

Therapeutics.—The question of therapeutics is a broad one and beset with difficulties, which vary with the age of the patient, and especially when we come to consider the question of submitting the parents to continued observation and treatment. In the case of the patient, the indication for specific treatment seems to exist in all cases where there are lesions of possibly syphilitic origin, especially if one or more undoubted stigmata are present. In infants and very young children a proper dietary is very necessary, especially of the supporting kind, for these children need soups or meat extracts at an earlier age than other young children. A mild mercurial ointment acts very well in the cases of infantile iritis, in promoting absorption and assisting to break up the adhesions to the lens capsule. The prognosis as to resulting vision will depend largely on the possible existence of chorioretinitis, vitreous opacities, and lesions of the retina and optic nerve. But these cases of syphilitic lesions of the deep structures of the eye promise much more to persistent and careful specific treatment than is usually supposed.

If there are other children in the family who show some of the marks of inherited syphilis, it would be eminently wise to subject the parents to prolonged specific treatment, in order, if possible, to eradicate

the taint and prevent the birth of any more tainted children. This would seem to be particularly indicated if the mother be again pregnant.

To illustrate what has been said upon the difficulties of diagnosis in these cases of tardy inherited syphilis owing to the absence of slight development of stigmata, I will give briefly the histories of a few cases.

Tardy Inherited Syphilis.

Case I.—A young girl, aged 14, was brought to me because her vision had failed, and it was thought that she was growing myopic. Without glasses the vision in the *right* eye was 10/200 and in the left eye it was 15/200. There was a myopia of D4 and an astigmatism of D1, axis 180°. With the correcting glasses vision in the right eye was 15/200 and in the left eye 15/50. The ophthalmoscope showed a very extensive chorioretinitis in both eyes, extending from the periphery all over the fundus in the *right* eye, but stopping short of the macular region in the *left* eye. In the ciliary and equatorial regions the process was in the atrophic stage, but nearer to the posterior pole there were fresh patches of exudation in the stage of efflorescence, and in the right eye a very large patch at the macula. In the left eye the patches of exudation were all comparatively recent, and the macular region was free. The patient was the picture of health, without any apparent marks of constitutional disease, but on a more careful examination several stigmata were found. There was a rudimentary crescentic notch in the two central incisor teeth in the upper jaw. There was a faint nebula in the right cornea, just below the center, only visible by strong lateral illumination. There were two small patches of pigment on the anterior capsule of the lens in the right eye, the remains of a former iritis. Rigid questioning revealed that the child had inflamed eyes when an infant of a few weeks old, the inflammation lasting for nearly a year. When the child was seven years old the right eye became again inflamed and the eye was practically blind for more than six months. This patient responded rapidly to constitutional treatment, so that in three months the vision of the *left* eye was 15/15 and in six months the vision of the right eye was 15/15, and the vision has remained normal for twelve years. A careful examination of other members of the family showed that two older sisters and an older brother presented unmistakable stigmata. One of the sisters showed an extensive chorioretinitis confined to the equatorial region in both eyes. Another sister showed slightly marked Hutchinson's teeth in both jaws and a small macula on each cornea. The brother showed three well-marked Hutchinson's teeth, and the remains of a former chorioretinitis with impaired vision. When closely questioned the father was ascertained to have contracted syphilis about a year before marriage and was supposed to have been cured, but he has at various times showed symptoms of the constitutional disease.

Case II.—A young lady, aged 27, consulted me in 1896 for failing vision in both eyes, stationary black spots in front of both eyes and photophobia. I had examined this patient ten years before and found a hypermetropia of D1, with an astigmatism of D 0.25, axis 90°, and normal vision, with a perfectly normal fundus. At that time I noted the presence of a square prominent forehead with protruding frontal bosses, and wedge-shaped incisor teeth, irregular in size and implantation, but without the crescentic notch. At the second examination in 1896, the vision was 15/30, in each eye, and she complained of a fog or mist before her eyes. The ophthalmoscope showed a most extensive chorioretinitis, extending all over the fundus of both eyes, some of the patches of exudation being recent and others in the atrophic stage, with marked pigmentation. The recent patches were near the macula in each eye, and there was an irregular central scotoma in the field of the *right eye*, its long diameter vertical, extending 20° above and below the fixation point and 10° to the temporal side. After careful questioning I found that at the age of two years the patient had had a general eruption all over the body, which lasted for nearly a year, and that recently she had had an eruption on the chest, abdomen, and thighs, which still remained in spots and was unmistakably a psoriasis. On questioning the mother, I learned that she had had two miscarriages before the birth of the patient, and had been delivered of a deformed stillborn child since the birth of the patient. The latter had been a frail child from birth with more or less constant ill health. By persistent treatment carried on for three months by inunction and potassium iodide, and the free use of iron and strychnia, the chorioidal process was arrested, the scotoma disappeared, vision was restored to the normal standard, and the patient's general health was very much improved. The cutaneous trouble was more obstinate and did not subside until nearly five months afterwards. The vision has remained normal ever since, but the fundus still shows the atrophic stage of chorioiditis desseminata.

Case III.—A lady, aged 28, came to me in 1902 with the complaint of failing vision in both eyes. The *right* eye had a myopia of D3 and vision under correction of 15/50. The *left* eye had a myopia of D1.50 and vision under correction of 15/30. She stated that she had no ocular trouble in infancy or childhood, and that she had always been able to use her eyes as she wished until three months before I saw her. A careful examination showed in both eyes a faint corneal macula on the temporal side. The rest of the media were clear in both eyes. There were two points of posterior synechiæ in the left eye and one in the right, but no ciliary injection and no swelling and discoloration of the iris. The ophthalmoscope showed a well-marked extensive chorioiditis in the active stage, most marked at the periphery, but extending well towards the macula. The adhesions of the iris were readily broken by atropia. This patient had no dental stigmata, the teeth being in exceptionally good condition. Her forehead was protuberant and square-shaped, and the vault of the hard palate was narrow and deeply arched. A brother and a younger sister had had inflamed eyes in infancy and again at puberty, and on examination both showed the Hutchinson teeth and the traces of an old interstitial keratitis. The mother had had several miscarriages before the birth of this patient, but none afterwards. The father was dead. Under persistent treatment the disease in the chorioid was arrested, and the vision was brought up to the normal in the *left* eye and nearly to the normal in the right eye, after *four* months' treatment.

Case IV. The last case was a young man, aged 21, who is still under treatment. This child was born healthy and had no ocular trouble until the age of twelve, at which time both eyes were inflamed, and he was out of school for a year. Since then there had been no disease of any kind until September last, when the left eye became severely inflamed, with pain and photophobia, and he was brought to me one week later. The *right* eye showed some faint nebulæ on the cornea, with normal iris and

fundus, a myopia of D3 and V = 15/50. The *left* eye showed an acute interstitial keratitis of the vascular type, occupying the center of the cornea, an iritis with adhesions below and no reflex from the fundus. The dental stigmata were wanting except for a wedge shape to the central upper incisors. The boy had evidently had a double interstitial keratitis at the age of twelve, from which he entirely recovered. After dilating the pupil in the left eye and breaking the adhesions, the ophthalmoscope showed an infiltrated vitreous and at the periphery some well marked patches of chorioiditis. The patient has a square forehead with protuberant frontal bosses. A younger sister of the patient had had an inflammation in both eyes at the age of fourteen, from which she entirely recovered and the cornea was now clear and the fundus was normal. She has the crescentic notch in the upper incisor teeth. The mother had had one miscarriage at the sixth month and had had one stillborn child, born at full term. I was not able to examine the father. The patient has responded well to rather severe medication and the vision of the left eye has improved to 15/100. The chorioiditis is slowly subsiding, and the corneal opacity is reduced to a small central patch.

In conclusion, it may not be amiss to state very briefly the substance of the therapeutical deductions which Fournier has drawn from his immense experience. He lays down four propositions, as follows:

1. Specific treatment is indicated in all cases in which the patients are actually affected by lesions or symptoms which might be due to syphilis, and who show at least one of the stigmata mentioned.

2. If a patient shows one or more of the stigmata mentioned, he should be subjected to specific treatment, as a prophylactic measure, even if there be no actual lesion present.

3. In a recognized syphilitic family, if a child has recently been born who presents one or more of the stigmata, the parents should be submitted to prolonged specific treatment, in order to prevent, if possible, the transmission of the inherited taint to any future births.

4. In case a woman becomes pregnant in a family in which the children previously born show some of the stigmata above mentioned, she is to be subjected to rigid specific treatment during her entire pregnancy.

In view of the many serious, even disastrous, lesions which have come under my observation, I feel inclined to add a fifth proposition to the four of Fournier, viz., that it should be made a penal offense for any syphilitic to marry.

THE TREATMENT OF INTRAPERITONEAL HEMORRHAGE FROM RUPTURE OR ABORTION OF TUBAL PREGNANCY.*

By HIRAM N. VINEBERG, M.D.,

NEW YORK.

Until lately there was an almost general concensus of opinion among gynecologists, at least in this country, that rupture or abortion of tubal pregnancy called for early or immediate operation. Of late, however, a note has been sounded in an opposite key, and we seem to have reached a time when the whole question has to be threshed out. In my opinion great benefit will accrue from such a discussion. The view seemed to be too prevalent that a patient, the subject of tubal pregnancy that had undergone rupture or abortion, would die from intraperitoneal hemorrhage if not operated upon post haste. I fear many lives have been lost, especially in the outlying districts of the smaller medical centers, from the practice which that view entailed. Hence it is that the two most important papers recently on deferred operation for the conditions under discussion came from operators who were so situated geographically as to be able to observe the harm wrought by the inculcation of that teaching. But when these gentlemen assert that patients practically never die from intraperitoneal hemorrhage from the rupture or abortion of a tubal pregnancy and that there is little or no risk in deferring the operation until the patient has had time to rally, I for one must take issue with them.

To enter into an intelligent discussion of the subject, we must digress for a moment and cast a glance at the pathology of tubal abortion and tubal rupture. The amount of blood poured into the peritoneal cavity from either condition is so variable that to discuss the subject in a general way would lead nowhere.

In the vast majority of the cases the interruption of the pregnancy occurs through the spontaneous bursting of the investing capsule. This is brought about not so much as a result of passive distention as through the erosive properties of the trophoblasts surrounding the young ovum. The breaking through of the invading capsule is always accompanied by hemorrhage to a greater or less degree whether the rupture occurs through the inner or outer wall of the tube. In the former instance, that is, when it breaks through the inner wall of the tube, the blood is poured primarily into the tubes and flows through the ostium-abdominale into the general peritoneal cavity, constituting what is known as tubal abortion. In the latter case, where it breaks through the outer wall of the tube, the blood is poured direct into the general peritoneal cavity, constituting what is called tubal rupture. In not a few instances both processes go on simultaneously, and bleeding may occur through the fimbriated end as well as through the tubal wall. The hemorrhage in either condition generally occurs at irregular intervals, as new points of perforation are produced by the constantly active and burrowing trophoblasts. In some specimens of ruptured tubal pregnancy on close inspection, one may find a number of pinhole perforations, many of which are closed by a plug of fibrin.

Now the amount of hemorrhage that may occur in a given case is purely accidental, depending upon the size of the blood-vessel which the trophoblasts have eaten their way through, or the size of the blood-vessel torn in actual rupture.

As a general rule the hemorrhage is less in tubal abortion than in tubal rupture. Still I, as well as others, have seen very copious intraperitoneal hemorrhage from tubal abortion and the literature contains reports of several cases of even fatal hemorrhage from that condition. Again in tubal rupture the hemorrhage may be slight and less severe than that which ordinarily occurs in tubal abortion.

When the amount of blood poured out is moderate a hematocele forms, which may be situated in the Douglas's cul-de-sac, the most frequent site, or at either side of the uterus, or even in front, as in a case observed by me. The affected tube containing a blood clot usually lies in the center of the hematocele. The rupture of the tube may oc-

*Read before the Medical Society of the County of New York, February 24, 1908, as part of a symposium on "The Immediate vs. Deferred Treatment of Hemorrhage from Rupture or Abortion in Ectopic Pregnancy."

cur between the layers of the broad ligament, and we then have a broad-ligament hematocele.

As a general rule, when an hematocele forms, there is no great danger of profuse intraperitoneal hemorrhage occurring subsequently. But such a contingency may occur either through the traumatism of an examination, as in a case of my own of which I will speak later, or through the renewed hemorrhage of such proportion from the affected tube as to break through the barrier of the investing capsule of the hematocele.

Occasionally with the inner rupture of the capsule of the young ovum the effusion of blood occurs in such a way as practically to disintegrate the trophoblastic layer. The process of erosion then comes to a standstill; there remains only an organized blood clot, of varying size, from an almond to an English walnut, or larger, attached to the inner wall of the tube. This clot would in time, in all probability, become almost entirely absorbed, and in this way nature would effect a cure.

If we were able to distinguish these cases they would form the class in which an operation would not be indicated. But as it is impossible with our present knowledge to differentiate them, they must be left out of consideration in our indications for operation.

In another class of cases, fortunately not large, either of tubal abortion or rupture, the amount of blood effused is so great that the whole abdominal cavity is inundated with blood, the abdomen being enormously distended, and the diaphragm pushed up to its greatest extent, crowding the heart and lungs so as to interfere with their action, and placing the patient's life in the greatest jeopardy or killing her outright within a time varying from one to twenty-four hours. These have been termed the tragic cases, but perhaps the term "cataclysmic" would be a more appropriate one.

In operating on these cases it is like cutting through the abdominal wall of a corpse, the tissues being practically bloodless. As soon as the peritoneum is reached it is found of a very dark color and bulging outward, and when incised the blood spurts out with considerable force.

I fear cases are frequently described as belonging to this class, when in reality they are nothing more than instances of copious or even moderate intraperitoneal hemorrhage with attacks of marked syncope. For instance, in Robb's twenty cases, reported at the last meeting of the American Gynecological Society, in five the condition was reported as serious and contraindicatory to immediate surgical interference. The lowest hemoglobin record in these cases was 60 per cent. In Simpson's cases the percentage of hemoglobin was 55 and 60 per cent. respectively. In the class of cases to which I have referred it would be difficult to make a hemoglobin test, for if one even could get a drop of fluid from the finger it would be like water.

It may be asked how are the non-cataclysmic cases to be differentiated from the cataclysmic cases. In my experience this can generally be done by watching carefully the behavior of the pulse. In the former class the pulse will show an appreciable improvement in quality and frequency within a few hours; in the latter class, on the other hand, the pulse will show no perceptible improvement with the lapse of time, but will become more rapid or become entirely extinct.

I think we are all pretty well agreed as to the treatment of the cases with or without copious intraperitoneal hemorrhage. I mean those in which the intraperitoneal hemorrhage falls short of the kind I have above described. They may be operated upon as early as expedient, or the operation may be deferred a few days, the patient in the meantime being kept under close observation.

It is the cataclysmic cases or those that are considered as such that form the bone of contention at the present time, whether we should operate upon them at once or wait for one or two or three days until reaction has set in, as advocated by Robb and others, or to wait still longer (for several weeks) until the reserve force is built up, the patient being kept in a state of hibernation with morphine and the most absolute rest, as advocated by Simpson of Pittsburg.

The latter proposition, that is, to wait for several weeks (45 and 47 days respectively in two cases), can scarcely call for serious consideration. Why it should be deemed necessary at the present day to keep a patient in a semimoribund state (deathlike stillness) to build up her strength so that she may withstand one of the simplest intraperitoneal operations the gynecologist has to perform is beyond my comprehension. I would not be understood by this, however, that operation in every case of ectopic pregnancy is a simple affair, some present technical difficulties as great as any met with in abdominal surgery. But they are the neglected and undiagnosticated cases, in which there have been repeated attacks of intraperitoneal hemorrhage, and in which the pelvic organs and a great part of the intestines are matted together into one indistinguishable mass. But the cases now under discussion merely call for opening the abdomen, seizing the affected tube, ligating and cutting it away, and removing as much of the blood as is found expedient and safe.

The other proposition embraced by the deferred operation, that is, to wait for twenty-four or forty-eight hours until reaction has set in, is worthy of our best attention and soberest thought. It is not easy to pass judgment offhand upon this question. There is room for an honest difference of opinion as to whether the best results are to be obtained by an immediate or a deferred operation in that sense. It is quite natural that each operator will be guided in this by the favorable experiences he has had with the one or the other method.

With the experiences I have gained so far with immediate operation in the cataclysmic cases, it would be a difficult task to convince me that my patients would have fared better had I waited for one, two, or three days. Of the 81 cases of ectopic pregnancy operated upon by me during the past ten years there were 18 cases with copious intraperitoneal hemorrhage. Of these perhaps only six cases should be put in the class which I have named cataclysmic. I have had only one death in the entire series of 81 cases, and that was in a case with only moderate intraperitoneal hemorrhage. The patient took the anesthesia badly, developed ether pneumonia shortly afterwards, and died on the twenty-first day after the operation as a result of this complication, while the process within the abdomen ran a perfectly smooth course, and the autopsy revealed a healthy condition of the peritoneal cavity.

It may not be amiss to relate the unfavorable conditions surrounding some of the cataclysmic cases of my series. In one case, which was as bad as any in the series, I found myself face to face with a woman dying from intraperitoneal hemorrhage, with only the kit of instruments I carry for an ordinary curettage. I had diagnosticated a probable ectopic pregnancy at a consultation with the family doctor the night before. Against my

better judgment and advice I allowed myself to be persuaded to come the next morning prepared for a curettage, and for an examination under narcosis, as the woman was very short and stout. Under narcosis I could distinctly palpate a mass the size of a hen's egg to the right of the uterus. I told the family doctor I was now certain of my diagnosis, but he insisted upon my doing the curettage. The curette removed distinct products of an early conception, and as the family doctor was standing behind as I was curetting, doubtless gloating over what he thought was my discomfiture, I noticed a distinct change in the color of the mucous membrane of the vagina. I called out to the anesthetist and asked him what the condition of the pulse was; he replied it was good. I continued with the curetting and in a few minutes the anesthetist called to me, saying he could not feel the patient's pulse. I jumped from my seat to look at the patient's face, and if I ever saw an exsanguinated woman I saw one before me then. Her face and lips were completely blanched. Actual death could not be attended with a greater degree of pallor of the countenance. In want of a scalpel I cut through the abdominal wall with a pair of angular scissors I had in my kit. The blood spurted up quite a height like a miniature geyser as soon as I cut through the bulging peritoneum. I passed down my hand in the pelvis, caught the right tube, which had a good-sized rupture at the isthmus portion, tied a piece of catgut around it near the horn of the uterus, and cut it away. I removed as much of the blood as I hastily could and closed the abdomen with tie and sutures of catgut. The peritoneal cavity still contained so much blood after the great quantity that had escaped from it spontaneously, and with what I had removed, that the family doctor could not be convinced that active hemorrhage was not still going on. But I felt confident his fears were unfounded. At the outset I had the husband telephone to Mount Sinai Hospital for a couple of internes to come at once with the intravenous apparatus and the ambulance. The internes arrived just as I was closing the abdominal wound. The patient was still pulseless and apparently lifeless. Each interne opened a vein in either arm and infused about 40 ounces of physiological salt solution. The patient was then placed in the ambulance and taken to the hospital, oxygen being administered en route. Shortly after reaching the hospital the pulse could be felt at the wrist, and, although she was very feeble for a few days she made a surprisingly rapid convalescence, had primary union of the abdominal wound and left the hospital a little after three weeks. The only complication she had was a breaking down of the intravenous wound of the right arm. The case, as you will have gathered, was one of these rare instances of simultaneous uterine and extrauterine pregnancy. I think it would be difficult to convince those who were present that the patient would not have died if I had lost any time waiting for reaction to set in.

Another of these cataclysmic cases occurred also in a case of simultaneous extra- and intra-uterine pregnancy. As the case has already been reported in the *New York Medical Journal*, February 24, 1906, I will state here in the briefest manner possible the salient points only bearing on the present discussion. Laboring under the mistaken diagnosis of a pelvic abscess, I examined the patient one morning to ascertain whether the time was ripe for a vaginal incision and drainage. Shortly afterwards I was hurriedly sent for and found my patient in a most alarming condition, with lips and face of a sickly livid hue, and the pulse about 100 and very small, the abdomen distended and the respirations shallow and labored. I, of course, recognized at once what had occurred, and had a prominent gynecologist in the neighborhood see her with me within ten minutes. He was opposed to immediate operation and advised morphia, ice-coil to the abdomen, and very careful stimulation. Instead of growing better the patient grew worse, so that four hours later the same consultant agreed that the only hope lay in operating at once. This was done, and as in the foregoing case, when the peritoneum was opened the blood spurted out with considerable force. An assistant was getting the arm ready for an intravenous infusion, but as soon as the abdomen was opened the patient's condition perceptibly improved, as was manifest by the color of the face and lips, and her pulse, due to removal of the great pressure upon the diaphragm and secondarily upon the heart and lungs. The case presented great and technical difficulties on account of extensive adhesions and the large raw surface created by the enucleation of the original hematocele, which I mistook for a pelvic abscess. The patient was in a very critical condition for several days, but finally made a good recovery.

The remaining four cases of the cataclysmic series presented similar features, and all promptly responded to the same line of treatment, operation as soon as it was possible, and the infusion into the veins of the arms of large quantities of physiological salt solution.

I wish to emphasize here that the intravenous infusion of salt solution skillfully and expeditiously administered by an assistant formed a very important part of the treatment. And I would like to repeat in this connection the words I used on a former occasion: "It is truly amazing to see in these cases how an apparently moribund patient can be brought to life by opening the abdomen, rapidly ligating the bleeding vessel, and injecting a large quantity of saline solution into the veins of the arm."

If it be said that these desperate cases which I have termed cataclysmic would not have died if left alone I can only say that that was not my impression, nor was it the impression of the several men who saw the individual cases; further, the literature contains numerous cases of fatal hemorrhage from tubal abortion or rupture, and everyone with a large experience has encountered one or more cases of the kind.

It is of significance that during the past ten years the only case of fatal intraperitoneal hemorrhage occurring in my practice was one in which operation was delayed against my advice until it was too late. The woman had been having symptoms of a ruptured ectopic pregnancy for several weeks, when one day at her place of business she fainted while on the toilet at about 6 P. M. She was brought home in a carriage. I saw her in consultation at 9 P. M., three hours afterward. The woman was very stout, was deathly pale, and had a pulse of 160, but which was still of a fair quality. I urged immediate operation, but could not obtain consent from the husband. He and the patient were willing to have it done next morning. The patient was placed in charge of a nurse and the usual treatment for intraperitoneal hemorrhage ordered. Next morning when we arrived prepared to operate, the pulse could not be counted at the wrist and evidences of extreme exsanguination were present. The patient was hurriedly placed on the table and expired in a few minutes after a few whiffs of

chloroform had been given and before I had time to open the abdomen.

Before closing I wish to make my position clear. In the vast majority of cases of rupture or abortion of tubal pregnancy it matters little whether the operation be done as soon as expedient or deferred for one, two, or more days. It is only in those very rare cases of abortion or rupture in which the amount of blood poured into the general peritoneal cavity is so overwhelming as to place the patient *in extremis* from anemia and pressure upon the heart and lungs that, to my mind, immediate operation with prompt intravenous salt infusion are imperative.

In illustration of how long a time may elapse before a case of that kind is encountered, I will state that during the past two years I have operated upon 28 cases (hospital and private), many of which were attended with copious intraperitoneal hemorrhage, but only one of them constituted what I considered an urgent or cataclysmic case. The remaining 27 cases were operated upon at my convenience or on the regular operating days of the service.

Still it is not my custom to defer operative interference more than a few days in any case of ectopic pregnancy in which I have been able to establish the diagnosis with a fair degree of certainty. And it is to the adherence to that practice that I attribute, in a great measure, the good results I have attained.

But in the kind of a case which I have above described as cataclysmic I would consider myself as devoid of surgical principle and of surgical courage if I failed to cut down at once with whatever means happened to be at hand so as to ligate the bleeding tube and thus arrest the hemorrhage.

751 Madison Avenue.

ACUTE LOBAR PNEUMONIA—A STUDY IN INFLAMMATION.

By G. K. DICKINSON, M.D.,

Jersey City, N. J

Pneumonia is king! Of all the diseases incident to germ invasion we have none more acute or more tragic in result. Perennial in appearance, unaffected by laws of sanitation, it has progressed in importance within the last fifty years so that instead of being eighth on the mortal list it now stands first. It exists in all climates and varies in intensity and death rate at different periods. Previous to 1850 it occurred more rarely and ran a fairly mild course, except in periods of epidemics, but since that time, according to statistics of the larger hospitals at home and abroad, it has become prevalent, and, in spite of the divers plans of treatment, the average death rate to-day is about 25 per cent.

A careful study of the natural and morbid physiological conditions relevant to this disease is most important in building up a rational form of treatment. The materialistic mind, quite common to the profession, is not satisfied with strict empiricism, though insufficient knowledge has made symptom doctors. The wonderful discoveries through laboratory research have so advanced our knowledge of physiology and pathology that a critical inspection of this type of inflammation will be most productive.

Health is due to the proper balance between the ever-present attack of pathogenic microbes and the normal resisting power of the individual.

In order better to comprehend the several phenomena incident to pneumococcal invasion of the lung it may be well to restate many well-known facts. The right bronchus is anatomically an extension of the trachea and passes down as a main trunk into the right lower lobe. The ultimate bronchioles are 1-125 of an inch in diameter and the air cells a little larger. Aeby estimates three to four million of pulmonary vesicles, with a superficial surface of one hundred and thirty square meters. These cells are possessed of a thin, delicate epithelial lining lying over the blood-vessels. Between the capillaries is a small, flat, nucleated cell. These lie on a basement membrane, and are connected by a cement substance, which, when in a fresh state, is clear, viscid, and semi-fluid. On inspiration pseudo-stomata appear between the epithelia which lead to the lymph-canalicular system of the alveolar wall, the latter consisting of striped muscle cells, branched connective tissue, and some elastic fibers. In the alveolar septa are capillary vessels—an exceedingly dense network—which may be exposed on both sides in contiguous air cells. The surface of the air cells is always moist and generally contains free eosinophiles, which in some way are connected with the nutrition of the alveolæ.

The air breathed at each inspiration is known as the tidal. The amount ordinarily taken in is 1-10 of the capacity of the lung. Still, on forced inspiration some of the fresh inspired air may reach a certain number of the vesicles.

The mucous membrane of the nose, pharynx, and bronchial tree are well fitted for the purpose of gathering up irritating particles, which, otherwise, might enter the lung. Fine particles of dust entering the lung may produce collapse of limited areas. Dust, odors, carbonic acid gas, and body emanations when breathed act reflexly, producing a protective dyspnea.

The respiratory interchange of gases between the tidal air and the residual is more rapid and complete when the outer air is cooler, the ratio being in proportion to the difference in temperature between the inspired air and that of the lung. Cool air passing over the nasal mucous membrane is a stimulant to the act of respiration, as is also a draught of cool air passing over the face.

The oxygen inspired is absorbed according to the rate of capillary circulation. Any excess of oxygen beyond that which the body needs will not be absorbed. Thirteen volume per cent. of atmospheric oxygen is necessary to raise the alveolar oxgyen tension to the point where normal oxygen absorption by blood occurs. Oxygen to reach the red blood corpuscles has to penetrate the moisture of the alveoli, epithelia, basement membrane, endothelium of the blood-vessels, and the serum—1-2500 of an inch.

The depth of respiratory movement varies inversely with the rate. The capacity of the bronchial tree being constant, in rapid breathing the tidal wave decreases. Respiration is regulated by a point in the medulla commonly known as the respiratory center, better termed the inspiratory center, which is activated by carbonic acid gas in the blood acting as a hormone from the tissues. This center has no anatomical entity.

The respiratory tract has a flora ever present and as varied as that of the digestive tract, but, conditions being different as to mode of entrance and environment, the resultant processes are not alike. This flora is that of the inbreathed air. Dust particles, holding bacteria, on being inhaled encounter the moist surfaces of the nasopharynx

and sinuses, the bronchi, and even the deeper structures. Tyndal has shown inspired air to be always full of floating particles, whereas the expired air contains none. These particles find on the moist surfaces conditions which do not stimulate them to activity; some are killed by the secretions of the part, others live a saprophytic life.

Those who have been brought in the neighborhood of desiccated pneumonic sputum will obtain an abundant growth of the same in the nasopharynx, which may persist for several months without further inhalation. Any germ existing in the air may be found in this locality. Experiments have discovered the germs incident to the pneumonic process even in the alveoli of the lungs without disease action taking place.

These germs are being expectorated from the mouth constantly. Those that obtain lodgment in the bronchi are driven up by the action of the cilia of the lining membrane. Those that reach the alveoli there encounter the leucocytes (often called "dust cells" because of their properties), which wander in from the blood-vessels and readily take up dust particles and attached microbes, carrying them through the lymph-canalicular spaces to the lymph glands.

Pneumonia, not being a specific disease, may be instituted by almost any germ which is able to proliferate in the air vesicles. Instances are known of pneumonic processes, with clinical histories very similar to that of pneumococcus pneumonia, caused by the diphtheria germ, the typhoid, the streptococcus, the staphylococcus, colon bacillus, and even moulds, but, in the large majority of cases of clinical pneumonia, Fraenkel's pneumococcus is found—sometimes alone, often with other germs.

The pneumococcus of Fraenkel is closely related to the streptococcus group. It occurs in pairs, sometimes strung together so that two, three, or four are attached in a chain. When grown in the laboratory on ordinary cultures, they do not generate a capsule, but when grown in the body, a pronounced capsule composed of mucin is always observed. It grows best in the presence of oxygen, but it can, by culture, be made to grow without. It is said that its growth is inhibited in pure oxygen. It does not secrete a toxin, so far as the present chemical methods have been able to discover, but does produce, through its action on surrounding tissues, lactic acid, and contains a very poisonous proteid. According to Gordon's method of chemical differentiation we have some nineteen strains of this diplococcocus, which apparently differ from each other in their pathological possibilities, for agglutinative tests prepared from one strain will not affect more than three or four of the group.

The factors which predispose to an attack of pneumonia, factors which disturb the normal balance of resisting power in the alveoli, are exposure to cold, particularly the dry winds of the northwest, fatigue, lowered nerve tone, and the breathing of fine irritating particles. Numerous investigations have been made into meterological statistics in the endeavor to find some connection between climatic conditions and pneumonia, but, so far as we have been able to discover, no one has worked it out for the one or two days preceding the first acute symptoms. Almost all have tried to associate them and the day of death, which, necessarily, will be unfruitful.

The deductions of many years of clinical observation should not be set aside without further research. Cold and walking against sharp winds may have their effect through disturbance of the vasomotor equilibrium, in the chilling of the body, or through the cooling of the cilia in the respiratory tract, inhibiting their action, or mayhap, through breathing into the pulmonary vesicles air insufficiently warmed, thereby instituting thermic trauma. Fatigue and nervous depression (somewhat similar conditions), may be effective through the trophic and vasomotor nerves of the lung.

There are three channels through which the pneumonic germ may gain entrance into the lungs. The principal one, and the most important, is the inhalation of an embolic spray of cocci-laden saliva from the back of the tongue, which, on account of anatomical conditions, is prone to be drawn into the right lower lobe. The tonsil may absorb adherent cocci, pass them into the circulation, thence to be carried into the air vesicles. Similar possibilities exist in the digestive tract. From this can be explained the fact that bacteriologists have been able to make cultures of pneumococci from the blood of people previous to the first clinical symptoms.

Calmette fed animals with pneumococci, which later were found accumulated in the lung with congestion, but intratracheal injection of pneumococci failed to produce pneumonia unless associated with the injection of irritating dust, or unless the system were depressed by shaving the animal experimented on and exposing it to cold.

Clinicians and pathologists who have described only the gross conditions existing in the pneumonic process divide it into several stages: that of hyperemia, of red hepatization, of gray hepatization, and the condition of purulent infiltration. These are the successive stages which appeal to the eye principally. In typical cases we find the solidification confined largely or entirely to one lobe. Very often, however, autopsies will show foci of infection in the remaining apparently healthy lobes on both sides of the body.

The extent to which the disease has progressed is as variable; for with gray hepatization we may find the red contiguous, and other places in a condition of hyperemia. The hepatized lung is enlarged to the extent of full inflation by the intraalveolar pressure of its contents. The weight of the lung is proportionately increased so that if one side be entirely hepatized it may weigh from two to four pounds more than the uninfected. The remaining unhepatized portion of lung may be normal in appearance and in condition even close up to the affected area, or may be edematous to the extent of becoming gelatinous. In all cases of pneumonia pleurisy to some degree exists, characterized by a deposit of fibrin on the pulmonary surface of the pleura.

How the pneumonia germ by its presence is able to initiate the sequence of conditions under discussion has not been decided. Various men, competent to give opinions, refrain from doing so, because as yet biochemistry has not been able to discover a toxin secreted by this germ. We know that its presence acts as an irritant; that in its neighborhood lactic acid is formed: that the germ is short-lived and on its death its contained proteid, which is very toxic, may be eliminated. One quarter of a milligram of the proteid from a very pathogenic strain may be lethal.

The first phenomenon histologically occurring

when Nature's barrier breaks down is due to the local irritation by the pneumococcus, leading to proliferation of the endothelial cells of the alveoli. At the same time some hormone enters the system, withdrawing from the bone-marrow leucocytes in increasing abundance, which accumulate in the neighborhood of the irritant.

Experiments by injecting *B. coli* into animals show that within ten minutes from the time of injection we have dilatation of the capillaries in associate parts. Undoubtedly in the pulmonary capillaries distention of the same and engorgement with red blood corpuscles occur shortly after the proliferation of the endothelial cells of the alveoli.

Wherever the pneumonic germ proliferates, hemorrhages are prone to occur; they occur in the alveoli, for with distention of capillaries we have rupture of the same and exudation of red blood cells into the air spaces. With breaking down of some of the epithelial cells and of the white blood corpuscles fibrin is formed, which seems to proceed from the alveolar walls into the mass of corpuscles. This process of exudation includes the terminal bronchioles. The stage of hyperemia has now passed into that of red hepatization, due to the presence of dilated blood vessels giving color. At the end of forty-eight hours the polymorphonuclear cells appear in abundance, and by their ameboid movements gain entrance to the alveoli. In the meantime the pneumonic germ has proliferated abundantly, so that by the time the polymorphonuclear cells appear they are most numerous and are at the stage of greatest virulence. The advent of the white blood corpuscles indicates the beginning of the stage of gray or non-vascular hepatization. With the advent of the polymorphonuclear cells now begins Nature's cure. All other conditions preceding are incidental to bacterial predominance.

This white blood cell finds the germ fully activated and in its most perfect culture medium. The attack begins in each cell encompassing a host of cocci. The endothelial cells that are proliferated also become phagocytic. The phagocytic cells in their hunger for pneumococci will encompass so many as to be distended far beyond their normal size. As is well known, phagocytosis of itself does not inhibit germ life. White blood cells also contain enzymes, which leave them either by a process of transudation or through solution of the continuity of the cell and enter into the plasma of the neighborhood. It is the presence of these ferments which aids in antidoting the pathogenicity of the microbe and materially assists in bacteriolysis.

The reactions later to be mentioned in relation to the blood, are, of course, relevant to the conditions existing in the alveoli. By the end of the third day, ordinarily, phagocytosis and enzymic action have proceeded so far that the local inflammatory process may be considered practically at an end.

Further progress of disease condition is now not so much inflammatory as it is toxic. Many of the germs have died; their contained toxic proteids have been liberated and have entered the surrounding plasma, to be carried through the lymph-canalicular spaces with migratory cocci, either alone or contained in phagocytic cells. Some, through inability to proceed centrally, pass to the pulmonary pleura and there set up the almost constant pleuritis.

Although bacteriologists have often found pneumococci in the blood before the initial symptoms, it is but a matter of technique to discover them after this stage. Largely in proportion to their abundance is the severity of the process. At the time the phagocytes were called by Nature's chemiotaxis to the irritated area, the other means of protection were also called upon. The plasma of the blood, be it understood, is not a simple fluid, but contains enzymic substances peculiar to every tissue in the body, consequently there is an immense complexity of tissue ferments, proteids, electrolytes, etc., therein: so that when the toxin or the toxic proteids enter the tissues, certain, as yet obscure, reactions take place. That which has been discovered is sufficient to give us some comprehension of this wonderful process. Gradually there are formed several important bodies, some of which already exist, others produced by the occasion.

Many bacteriologists have worked on the blood serum in the endeavor to discover its chemistry. The natural result is many theses and quite as many opinions pertaining thereto. That which is accepted universally should be known to each individual practitioner and be as thoroughly comprehended by him as are the grosser lesions which naturally come to mind in physical diagnosis.

The pneumococcus, secreting no toxin and containing only a toxic proteid to be discharged when the germ ceases to exist, does not induce the formation of an antitoxin, so the contained ferments in the plasma are our only reliance for recovery.

Phagocytic cells contain cytases which are not bacteriolytic but inhibitive. Exploded or disintegrated leucocytes discharge substances known as alexins which are also bactericidal, but do not act effectively without the presence of what is known as intermediary bodies.

The coccus and the substances produced by it in the lung lead to the formation of numerous not well-understood antibodies, which originate in the blood-forming organs.

Another ferment, called agglutinin, possesses a physiochemical reaction, leading to the clumping of the cocci and often solution of their content.

As at present comprehended, the most important substance is the opsonin, an intermediary body formed from the various body cells, which has an inhibiting effect upon the coccus so that when engulfed by the phagocyte its contained bacteriolytic enzymes may complete the destruction of the germ. Thus Nature's defense is antimicrobic.

The time necessary for the formation of sufficient opsonin, agglutinin, and antibodies to enable the phagocytes to accomplish their result is the length of the disease process proper.

The crisis of the disease occurs at that time when these substances obtain the upper hand. Such is Nature's method of cure, and without this process, without the opsonins, or the agglutinins to assist the phagocytic action and the antibodies, the crisis does not occur and death may and probably does follow.

As soon as the crisis has occurred, as soon as the battle has been fought and won by Nature, then comes the process of elimination of the different toxoids in the blood and the absorption of the pneumonic exudate and its elimination. This process of absorption is heterolysis, that is, the mutual fermentive action of one extraneous product upon another in the presence of leuco-

cytes and electrolytes leads to their softening and the gradual passage through the lymphatic system into the blood.

During pneumonia the chloride of sodium output is diminished and often absent, because of its retention in the system, no more in the lung than elsewhere; nevertheless, its presence in the lung is of vast importance. Chloride of sodium is an active electrolyte and easily becomes ionized. The electrolytes put life into the proteids and without their presence active tissue changes would not occur.

As soon as the crisis has passed we have the nitrogen output increased and the chloride of sodium in proportion, while the leucocytes promptly diminish in number.

In addition to the local effect of the germ mighty influences are brought to bear in various ways upon the economy in general. After one or two days' intubation, tissue and microbic poisons, of amount sufficient to produce fever, rapidly accumulate. The sudden influx into the system of these materials produces a vasomotor reflex disturbance so severe that the peripheral capillaries contract and the volume of blood is largely thrown into the abdominal cavity. This condition is clinically known as the chill or rigor. Although it is the first symptom ordinarily recognized, a careful study of individual cases, where possible, will show minor respiratory lesions: tonsillitis, indicative of pneumococcus invasion through the tonsil; tracheobronchitis, often induced by the pneumococcus, gastroenteritis suggestive of entrance by this means, or conditions of malaise, with rise in temperature.

After the first phenomenon respiration becomes more frequent, its normal relation to pulse-rate being disturbed. In the first two or three days of the process this increase in rapidity of breathing is brought about by three factors: irritation of the pulmonary branches of the vagus by the inflammatory reaction, the presence and accumulation of carbonic acid gas in the blood which stimulates the inspiratory center, and fever. Where the pneumococcus has invaded the pleura, the distress incident to this condition prohibits deep breathing. As we may have high fever or even moderate accumulation of carbonic acid gas without acceleration of respiration, the most important factor is the vagus.

After the third day when the picture changes dyspnea may ensue, accompanied by cyanosis. Urgency in respiration is brought about by the continuance of the conditions mentioned, to which may be added the effect of toxins on cerebral centers and heart, extent of lung involvement, bronchitis, and edema of infected area. It is said that in pneumococcus pneumonia edema is rare, it being generally found in the atypical types.

Carbonization is a terminal condition and is brought about by a combination of conditions, stimulation of the vasomotor center by carbonic acid gas, consolidation, and pleuritic pain. In severe cases continued and excessive irritation of the cerebral centers may lead to the breaking down of these mechanisms.

Fever is a condition incident to failure of the heat regulating apparatus. Not until the temperature of the body exceeds 104.5 degrees has this disturbance proceeded to the extent that exhaustion of the thermogenic center may be affected or degenerations in the important tissues of the body occur. In most diseases that are recoverable, the temperature does not rise for any length of time beyond the amount stated. Experiments have demonstrated that in a warm animal the disease runs a more rapid and sthenic course than in a chilled animal. Clinical experience shows a more prompt and lasting crisis where the local process has been intense, as indicated by high continued fever. Laboratory experimentation proves a more prompt formation of the antibodies, agglutinins, and opsonins.

The cardiovascular apparatus is not affected alike in all cases. When we consider the several strains of pneumococcus, with possibility of accompanying germs of divers types, and the extent of disease induced, the different qualifications for reaction (local and systemic—normal in some individuals and pathological in others, as in the aged and the alcoholic), small wonder is it that this apparatus varies so markedly in its sustaining and resisting powers. The pulse is quickly affected, being more frequent and full. As the disease progresses it becomes small and weak. High arterial tension is a rare condition in the early stages. It may be subnormal, but with beginning carbonization and passing on to pronounced cyanosis, the pressure rises, due to the accumulation of blood in the venous channels. Finger determination of arterial pressure is inaccurate. Medical attendants fail to recollect that systolic high pressure into dilated blood-vessels impresses the examining finger as though high arterial tension did exist. Observation with the more accurate instruments fails to confirm this.

The heart is a most important organ, naturally, in this pathological complex—its nerve mechanism, first stimulated by the toxin, then weakened by lessened nutrition under increased venosity, its muscle degenerating as do the other tissues of the body, its endothelium irritated and hyperplastic in the production of phagocytic cells, and strained, particularly on the left side, by the gradually increasing venous pressure from behind and the obstruction ahead—hence it must be watched, aided, and at no time debilitated by treatment. Death occurs through its failure either by degeneration of its muscle or distention of its chambers.

Sometimes toward the end of the disease, or even after the crisis, pneumococci that have been in the blood find lodgment in various organs of the body. When lodged in the stomach or intestines a local inflammatory reaction is induced, often hemorrhagic, inducing a gastritis or enteritis which may be fatal in the weakened state of the individual. It is claimed that the pneumonic germ is always found in gastric ulceration. In the liver or kidney, as in the heart, cloudy swelling may occur, degeneration of tissue, and at times pus foci. In a certain percentage of the cases the effect of eliminating nitrogen products, toxins, or ill-advised medicaments may produce a desquamative nephritis of more or less virulence.

Whereas, the profession with fair uniformity is agreed as to the facts and hypotheses cited in the text, when it comes down to treatment we find it as varied as the individual mind. The manner in which the individual receives a statement into his mind depends upon his receptivity, which is a personal factor, and we naturally try to adjust the new to our preconceived notions. It has been said that "physicians suffer from an incurable disease, that of building up complete forms of treatment of diseases under observation from inadequate facts eked out by vivid imagination." Hip-

pocrates has said "experience is fallacious and judgment difficult."

It will be interesting to deduce from the statements presented in this paper a plan of treatment and then see how it compares with the most approved methods of the day.

Pneumonia, being a microbic disease, the patient is a center for dissemination, consequently all cases sould be treated from this viewpoint. Seclusion, sanitary cleanliness, and destruction of sputum should be rigidly enforced. After the disease has gone, disinfection of all objects possibly reached by the expiratory spray is in order. As each individual supposedly infects himself from germs lodged in his own air-passages, something may be accomplished with gargles, such as alcohol with glycerin and bicarbonate of sodium. The sinuses connected with the nasopharynx, of course, cannot be reached. Their importance, however, can be judged when in 91 per cent. of deaths from pneumonia active sinusitis is found.

Nature's method of holding the disease in check, of establishing a cure and promoting convalescence is so well adapted for the occasion and so wonderfully complete, that the physician of today, and probably of the long future, will be compelled to sit by the bedside in admiration of the process, satisfied to do that which may assist Nature and studiously avoiding any treatment, pharmaceutical or non-pharmaceutical, which would tend to interfere with her methods.

"No branch of therapeutics holds out better promises than that which is based on natural methods," says Campbell in the Croonian Lectures. That is, increasing the opsonic power. Treatment by drugs, dating back as it does for thousands of years, has, with few exceptions, yielded but barren results. The whole art of healing consists in acting directly on brain and nerves, relief of peripheral irritation and in curing a faulty plasma, nothing more or less. It may be summed up in the aphorisms "tend the mind and the nerves; correct the plasma."

In the treatment of the individual we must ever recollect that pneumonia is a process not a condition, being a disease of short duration where the phases change from hour to hour. The most important points to bear in mind are the nerve tone, respiratory interchange, the economy's reaction as expressed in the serum, and the condition of the heart.

The pendulum has swung many a time in the experience of most physicians only to return. But the swing of the pendulum towards fresh *live* air in the treatment of pneumonia is hardly apt to return because it is impelled by proven physiological laws.

A patient placed where he will breathe "uncooked" air, whose sensitive nostrils will not be offended by house odors, carpet dust, and body emanations from himself and the attendants, and where in addition his nerve tone, particularly the inspiratory center, will be invigorated and sustained by the flow of cool air over his face, and the respiratory changes activated by the difference in temperature of the inspired air, will receive a treatment far more potent in value than anything pharmaceutical.

It is very important to protect the body against chill. Any such tendency must be obviated by heat to the feet and limbs. Gentle perspiration steadily maintained equalizes the circulation, prevents vasomotor disturbing waves, and postpones to some extent the dreaded carbonic acid accumulation.

Throughout the disease avoid unnecessary treatment of conditions which, though prominent, carry no serious import. The bounding pulse of the inflammatory stage need not be treated by medication. Sedatives, such as aconite, veratrum, and the coal-tar products should be avoided even though their primary effect may be agreeable to the patient and attendant. It is hardly wise to give any sedative to an organ which in a very few hours must stand an enormous strain.

When dyspnea and cyanosis are severe vascular tension becomes high. More blood is thrown into the right side of the heart than it can discharge. If the heart muscle remains unaffected by the toxins, its function may not be compromised, but, if the back pressure be too great or the muscle undergoes granular degeneration, then dilatation may occur. In some cases venesection is proper. Digitalis, though slow in action, is never harmful. Where the possibility of this condition is surmised, begin this drug one or two days before it is really needed—never more than a grain of the powdered leaves every three hours and for not more than three days at that rate.

The diminution in tidal air, brought about by rapid breathing and pain, tends to promote the accumulation of carbonic acid in the air-cells. Relief of pain by the application of aconite stupes or heat or cold will enable a longer and deeper inspiration. The value of oxygen has been much discussed. Among a number of practitioners the tendency as to advise its disuse. Personal experience can say nothing for it except that which is in its favor. It is but natural that an inspiratory wave surcharged with oxygen should increase the oxygen tension in the alveoli and diminish the carbonic acid. Without fail, begin its administration at the very first indication of increasing carbonization; do not wait until the heart feels its effect; do not wait for dyspnea. Fortunately, however, with the patient's face in the open the indications for its use are greatly decreased.

Avoid chlorides of any type, particularly if the kidneys fail to eliminate them, for pulmonary or meningeal edema may ensue.

Sometimes before the crisis gastrointestinal complications are pretty apt to arise. A careful outlook should be kept for the possible acute dilatation of the stomach, which is a complicating factor more often than is surmised. Intestinal toxemias should be promptly relieved by mild purgation.

The supreme factor in treatment is the serum. Leucocytes, except in the very pathogenic types of pneumonia, do not fail, but the ferments peculiar to the serum, though present in the normal individual, require several days for their sufficient elaboration. All treatment therefore should be directed towards the prompt formation of these substances. The opsonins in particular are easily influenced by various conditions. Sleep and mental and physical comfort materially assist in their formation. A quiet, sympathetic, and attentive nurse, congenial surroundings, and the assurance of recovery are not unimportant factors for their formation.

Vaccination after the plan of Wright with dead pneumococci obtained by culture from the pharynx is a logical procedure and has been reported as successful.

It has been shown that several drugs ordinarily administered during the course of this disease are potential for harm. Alcohol, for instance, will quickly reduce the opsonic index. Another action of alcohol is that it is quickly absorbed from the stomach without being acted upon by the digestive fluids, and, passing into the liver inhibits that organ's function as a toxin destroyer. Our best clinicians do not resort to it until the crisis, but even then it may be harmful, for, if there remain any pathogenic germs in the lung with the opsonic index cut down too promptly, relapses may occur.

Opium, aconite, and large doses of quinine inhibit the ameboid movements of the white blood corpuscles. Small so-called "tonic" doses of quinine, however, have a contrary effect. Water should be given liberally for its flushing effect.

As the pneumococcus brings about the formation of acids in the lung and catabolism of body-acids in the tissues, some alkaline is valuable through the entire course of the disease; the ammonia preparations are perhaps the best type. They further tend to forestall heart clot.

The historical importance of the present attitude of practical medicine is not fully appreciated. After centuries of empiricism with an occasional glimmer of light which but made the darkness darker, our hopes were raised by the discoveries in physiological therapeutics. Not long was it, however, before limitations again were discovered; so now disease treatment includes all that pertains to empiricism, drug action, serum treatment, and body sanitation.

Let us know Nature's methods and respect them, aiding her in every way by good nursing, soothing nerve distress, and not add poison to toxemia.

NOTES ON CHRONIC RHEUMATISM AND ITS TREATMENT.

By J. DARDEL, M.D. (Paris).

Consulting Physician at Aix-les-Bains (Savoie).

While no doubt a great deal remains to be elucidated in regard to the etiology of the diseases grouped under the somewhat elastic term chronic rheumatism, the data actually in our possession are sufficient to enable us to take a broad view of the subject, and in many instances to formulate the appropriate treatment, whether prophylactic or curative.

It is indispensable to a proper comprehension of the pathological problems which we propose to discuss to subdivide cases of chronic rheumatism into various clinical forms, and this tendency has become even more manifest during the last few years. One is naturally tempted to suggest a classification based on one's personal experience, but this practice, if generally followed, would inevitably result in "confusion worse confounded," and we prefer to adopt the classification which approximates most nearly to our own conceptions, with liberty to modify or amend descriptions which do not appear to us to be strictly accurate.

The affections included under the head of chronic rheumatism in many instances differ widely from each other; indeed, so difficult is it to tabulate these varieties on any uniform plan, that Teissier and Roque brought forward a classification based on the supposed etiology and pathogenesis, leaving the clinical manifestations to take care of themselves. From this point of view cases of chronic rheumatism may be divided into three principal groups: (1) chronic, progressive, deforming rheumatism (Trousseau's *rhumatisme noueux* and Besnier's *osseous rheumatism*), (2) chronic forms of rheumatism following acute or subacute articular rheumatism or secondary to infection of some kind, (3) chronic rheumatism of a dyscrasic or toxic type often described as rheumatic gout.

Progressive, deforming rheumatism or arthritis deformans is usually attributed to the influence of damp, and many authorities hold that this etiological factor is capable of determining the disease apart from any infection or preexisting constitutional disturbance. That damp plays an important part in precipitating this variety of chronic rheumatism we are not willing to deny, but it can at most be but one factor in its production; in other words, there must be a suitable soil, and the salient feature of this soil is chronic malnutrition. A general survey of the conditions under which the disease makes its appearance appears to justify the assumption that it may be determined by the long-continued action of malnutrition in arthritic subjects who happen to be exposed to damp. This would explain why arthritis deformans is most frequently met with in elderly persons belonging to the poorer classes. It is occasionally met with among the better classes, but of course malnutrition is present just as much when the patient is unable to assimilate food as when he is unable to obtain it.

Deforming rheumatism may attack one or several joints, one of the most interesting forms being that in which the vertebral joints are involved, "rhizomelic spondylosis." Some authorities consider that the underlying cause of the disease is an obscure, and as yet unproved, affection of the nervous system, while others suggest that cold and damp may vitiate metabolism with the formation of toxins that act as irritants to the spinal meninges. The evidence brought forward of the presence of such toxins and the action on the meninges is, however, to put it mildly, inconclusive, so that after all we are reduced to conjecture, all the more so seeing that the post-mortem appearances are disconcertingly inconstant. Taking the whole of the circumstances into consideration, it is difficult to resist the conclusion that this variety of chronic rheumatism is an infective or toxic trophoneurosis.

The second group comprises cases in which chronic rheumatism follows acute or subacute articular rheumatism, as well as infections associated with articular manifestations, such as gonorrhea and tuberculosis, or, more rarely, the eruptive fevers (especially scarlet fever) and dysentery. We are indebted for our knowledge of the etiological importance of tuberculosis in the production of rheumatic manifestations to Poncet, who has opened up a fresh field of investigation.

Lastly, we have the cases in which chronic rheumatism appears to have a dyscrasic or toxic origin, the so-called rheumatic gout. This form is assumed to be dependent on autointoxication with uricemia, and is closely associated with what Huchard calls delayed nutrition. It gives rise to various dermatoses, gravel, etc., and is met with principally in individuals the subjects of that special constitutional state known as "arthritism." This group comprises articular deformities arising in connection with dilatation of the stomach (Bouchard's nodes), interstitial nephritis, biliary infection, and cholemia.

These subjects are very prone to circulatory disturbances, with heightened arterial tension, aortitis, and renal sclerosis.

In view of the diversity of the etiological factors and clinical manifestations of the different forms of chronic rheumatism, it is hardly necessary to point out that there can be no one treatment, since each cause and each effect must come within our purview. Ignorant as we are of the exact pathology of certain forms, the treatment is necessarily in great measure symptomatic, and is consequently to be adapted in each case to the requirements of the individual patient. Beginning with considerations on general hygiene and therapeutics, and the hydromineral treatment, we shall pass on to deal with the special therapeutic indications in the different forms of the disease.

1. *Hygienic and Dietetic Treatment.* — Strict hygiene is the basis of treatment in all forms of chronic rheumatism, and as cold and damp are powerful factors in determining its incidence, our first care must be to see that the sufferer is protected against their untoward influence. As far as possible the patients should avoid living on the ground floor, especially in narrow streets or overlooking courtyards. The dwelling apartment should face south, the bedroom should be large and airy and the bed must not be placed against the wall. Ventilation should be insured by an open fireplace and ample window space, for light and fresh air go together. If the structure of the house be defective, *i.e.* lack of damp courses or absence of cellars, if the house be situated on a clay soil or in proximity to ponds or marshes or too closely hemmed in by trees, the patient must be advised to change his residence. Rheumatic patients should wear woolen undergarments at all seasons of the year, and affected joints must be protected by flannel bandages. As it is of the greatest importance to maintain the skin in a state of functional activity, the patient should be well rubbed with a horse hair glove or Turkish towel moistened with spirit (eau de Cologne) every morning. Regular exercise short of fatigue is indispensable, with special provision for movement of the affected joints. It is hardly necessary to remark that we do not recommend exercise directly after an attack of acute rheumatism, or for some time after an acute exacerbation in the course of chronic rheumatism. Apart from these considerations, methodical exercise of the stiffened joints is an essential part of the treatment, especially in arthritis deformans. As bearing on this point it is worthy of note that deformities are much less pronounced in the right hand, a fact which Charcot attributes to its being more actively employed than the left. In this way we may avert the tendency to ankylosis that characterizes certain forms of chronic rheumatism. It is necessary to insist on this point because, owing to the pain and discomfort associated with movement, patients are often very reluctant to comply with this advice.

Diet is a matter that must be thought out in each case. In progressive deforming rheumatism the patient is generally very debilitated as the result of chronic malnutrition, hence the term "poor man's gout" often applied to this form. Such patients require a generous, stimulating dietary, and much benefit attends the administration of cod-liver oil. Moreover, these patients are peculiarly liable to develop phthisis, and this is a further indication for improving nutrition. Inasmuch, however, as they not infrequently suffer from chronic Bright's disease, it behooves us to examine the state of the kidneys before giving large quantities of nitrogenous food.

The same necessity for liberal nourishment obtains in cases of rheumatism associated with infection, whether the infective agent be rheumatic fever, gonorrhea, or tuberculosis.

In dyscrasic or gouty rheumatism the problem changes. The sufferers are often persons addicted to overeating, associated, it may be, with sedentary habits of life. The first indication, therefore, is to restrict the amount of food, forbidding excesses of all kinds. As a rule, they may be put on a mixed diet, merely restricting the intake of nitrogenous food and alcohol. It is not so much the kind of meat as the quantity that we have to consider. Beef and mutton are, however, preferable to veal and game; pork (except lean ham), fats and the flesh of young animals, such as kid, lamb, etc., should be altogether forbidden. Fish is admissible, with the exception of salmon, cod, and shell fish. Eggs and milk in moderation along with green vegetables. Tomatoes used to be prohibited on the ground that they contain oxalic acid (like celery), but the validity of the objection is open to question. Much the same thing may be said of spinach and asparagus since authorities are far from unanimous in reference thereto. Farinaceous articles may be taken—potato, macaroni, and the like, but bread should be well baked and thoroughly masticated. Fruit is best taken cooked, with milk or cream in lieu of sugar. All spices and condiments are to be avoided on the ground that they disturb digestion, but lemon juice in moderate quantities is a useful, refreshing beverage. In the matter of drink, pure water is unquestionably to be preferred, but for persons with poor appetite and slow digestion, a small quantity of a light wine (preferably white) may be allowed. Heavy beer and wines are injurious, and in France, at any rate, it is customary to discountenance spirits, even when diluted. These general rules will have to be modified in deference to individual requirements, especially in the presence of indications of nephritis.

The general prophylactic and hygienic treatment of chronic rheumatism may be summed up as follows: Strict attention to personal hygiene, special precautions in respect of dwelling and clothing, regular exercise with special attention to affected joints. In progressive deforming rheumatism and in the forms following infection, liberal nourishment with close surveillance of the state of the kidneys. In dyscrasic or gouty rheumatism, a dietary strictly regulated in respect to quantity and quality.

2. *Medicinal Treatment.* — The extreme chronicity of these affections is apt to discourage both patient and physician; nevertheless there are certain drugs which experience has shown to be beneficial. The therapeutical indications will vary, of course, according as the disease is in an acute or a chronic stage. A volume might be devoted to the innumerable methods of treatment that have been recommended at one time or another, so that I shall limit my remarks to the use of remedies, the beneficial effects whereof are within my personal experience.

There is no doubt that in acute and subacute rheumatism, in addition to local applications to be described later, bicarbonate of sodium and quinine afford marked relief. Charcot was in the habit of prescribing large doses of bicarbonate of sodium, an ounce or more in the twenty-four hours, but although we still make use of the salt it is in much more moderate doses. I believe that all the good effects can be obtained by giving it in doses of two or

three drams in divided doses daily. Sulphate of quinine, when well borne, is valuable on account of its specific and tonic action, but it is rarely necessary to exceed ten or twelve grains a day in divided doses.

In spite of the fact that the salicylates do not act as rapidly or as constantly in chronic as in acute rheumatism, they are often employed, and they are useful in that they tend to mitigate the painful manifestations when present. The possibility of inducing renal disturbance with these drugs must never be lost sight of, and the renal function must be closely watched before and during their exhibition. Various coal tar preparations are also employed on account of their analgesic and antiperiodic properties, but it is very doubtful whether they exert any curative effects. In patients with gouty antecedents, personal or parental, colchicum often brings about an improvement, but there remain a number of cases in which none of the foregoing afford relief, and we are obliged to have recourse to opiates.

In what may be called the quietly progressive forms of the disease, the two great remedies are iodine and arsenic. They require, however, to be given in comparatively large doses, and their irritating effects on the gastric mucosa render administration by the mouth admissible only exceptionally. Thanks to pharmaceutical progress, it is now possible to give both iodine and arsenic by intramuscular injection, thus avoiding the inconveniences associated with their exhibition *per os*.. If preferred, however, we may have recourse to compounds of iodine with peptones, which contain a large proportion of iodine, and are comparatively unirritating. The introduction of the cacodylate of sodium and its numerous congeners enables us to employ arsenic with the greatest ease whenever indicated. I usually administer from one-half to one grain in a sterilized solution daily for ten days followed by a week's interval, and another ten injections, this time allowing an interval of at least a month. Under the influence of this treatment, very marked improvement often ensues in respect to both general nutrition and local lesions.

In some instances, however, the iodides appear to yield the best results especially when there is high arterial tension. The sodium salt is to be preferred to the potassium salt in presence of marked asthenia, and should troublesome coryza supervene my usual plan is to increase the dose, for, curiously enough, the symptoms of iodism other than gastric often subside when we double or treble the dose. In this way I sometimes give as much as fifteen to twenty grains daily without inconvenience, associating it with bicarbonate of sodium and a vegetable bitter. It is well to suspend the administration for a few days from time to time in order to avoid accumulation. When there is much anemia, iodide of calcium or iodide of iron may be employed.

Iodine and the iodides can be associated if desired, as in the following formula: Iodine gr. xxx, iodide of potassium gr. lxxx, rectified spirit fl. oz. i. Begin with five drops thrice daily in water or milk or wine, gradually increased to thirty or forty drops daily, with an interval of a week once a month. Gram's saturated solution is suitable for hypodermic injection, if preferred. It contains iodine 1 part, iodide of potassium 2 parts, distilled water 100 parts; one to three cubic centimeters for each injection. Various organic combinations of iodine and oily solutions are also in use. The iodine in the last named preparations is eliminated much more slowly, so that their action is maintained much longer than that of others, which is an advantage. The oily solutions may be given by the mouth or hypodermically; the injections are quite painless. The choice of the particular preparation will be determined in great measure by the tolerance of the patient. It must be remembered that intolerance of one preparation does not entail inability to tolerate others, hence the value of a variety of formulæ. Among other drugs that have enjoyed a certain popularity in the treatment of rheumatism may be mentioned guaiacum and phosphoric acid. These have yielded good results in some instances, but we are not at present in a position to define the precise cases in which they are to be preferred.

In rheumatic gout alkalies are useful to combat the hyperacidity, but it is easy to overshoot the mark, and it is well to suspend their administration from time to time in favor of valerianate of ammonium or piperazine. One sometimes meets with cases of chronic rheumatism associated with myxedematous symptoms, and in such thyroid extract has appeared to be of benefit, doubtless by accelerating nutrition.

It will be seen that the main object of medicinal treatment is to stimulate nutrition, thus improving the general health, the local lesions being dealt with by topical measures.

3. *Local Treatment.*—The object of local treatment is to alleviate pain, to diminish the local inflammatory reaction, and to restore mobility to the affected joints. One of the most valuable sedatives to allay the pain during paroxysms is salicylate of methyl, as in the following formula: Salicylate of methyl and chloroform āā 20 parts, camphorated oil 100 parts; or we may prescribe equal parts of oil of wintergreen and olive oil.

As a palliative measure liniments of belladonna are often of service or the extract of belladonna may be applied on hot compresses, to be renewed every two or three hours or oftener if the pain be severe. Dieulafoy recommends poultices with or without belladonna or laudanum. His favorite application was bread crumb that had been softened in water, gently heated for three hours and reduced to putty-like consistence by kneading with camphorated alcohol. Covered with protective, this may be left on for some days. This treatment is specially beneficial in subacute infectious rheumatism. Garrod, on the other hand, employed ammoniacum and galbanum plasters to the affected joints. When counterirritation is desired, nothing is better than tincture or liniment of iodine, blisters having fallen into disrepute.

General massage is of service in chronic rheumatism, in that it stimulates nutrition, but massage of affected joints and active movements thereof are not advised, since they often provoke a recrudescence of the pain; at any rate, they should not be used until some time after all inflammatory symptoms have disappeared.

Even in progressive deforming rheumatism (rheumatic arthritis) active movements may excite an acute exacerbation. It is just this question of deciding at what period massage and movement may advantageously and safely be employed that physicians have to consider, and only long experience enables one to form a trustworthy opinion.

Heat and electricity are variously employed in the treatment of chronic rheumatism, hot sand, warm mud, superheated water, the local application of hot air or vapor, heat generated electrically, and the electrical current, including high-frequency

currents. They all have their utility, and the choice between them must necessarily be determined by circumstances.

4. *Mineral and Thermal Waters.*—That the thermal treatment is beneficial in most forms of chronic rheumatism is evidenced by many centuries of practical, if empirical, experience. What modern research has done has been to distinguish between the various forms of the affection and to decide which is the most appropriate mode of dealing therewith. Thermal waters act in two ways—general and local. In some forms—rheumatic arthritis for instance, in which the general nutrition is poor—the constitutional effects are the most important, while in others—monoarthritis for instance, in which the state of the general nutrition may be fairly good—we rely much more upon the local action of the waters.

There are certain contraindications, such as noncompensated cardiac disease, arteriosclerosis, and advanced kidney disease, but none of them is absolute. The question indeed turns upon the actual condition of the patient rather than upon the particular disease from which he is suffering. It follows that the so-called contraindications are merely so many reasons for prudence in organizing the treatment and for close surveillance during its continuance.

It is generally agreed that the thermal treatment should not be commenced too soon after an acute attack, in fact not for some weeks after the pyrexial symptoms have subsided. I cannot help thinking that the mode of application of mineral waters possesses much more therapeutical importance than the mineral constituents, although these of course may play a subordinate part in effecting a cure. Not only so, but much benefit accrues from the change of environment and occupation or absence of occupation. Dyspepsia and nervous exhaustion are such common factors in all forms of chronic rheumatism that rest, outdoor exercise, and change of air, with an appropriate regimen constitute an integral part of the treatment. Alkaline and sulphur waters give the best results in the treatment of most forms of chronic rheumatism, but the former are contraindicated in the victims of chronic malnutrition on account of their lowering tendency. Sulphur waters, on the other hand, are stimulating, alterative, and depurative and can be adapted to suit individual requirements, whether the patient be suffering from malnutrition or not.

The thermal treatment, as practised at Aix-les-Bains, has served as a model for similar establishments all over the world. Tradition and continuous observation have perfected our knowledge of their action and of the mode of application, with results that are of world-wide fame. The treatment at Aix comprises hot and cold douches in association or not with general or local vapor baths or sulphur baths. The douches for the most part are combined with methodical massage under water, applied under instructions laid down by the physician. The local vapor baths (Bertholet) are also followed by massage when so directed. The "douche massage" may be regarded as the Aix specialty.

The temperature of the springs, which supply upwards of a million gallons daily, is about 45° C., and the water issues at varying degrees of pressure, so that it is subservient to all requirements. After the douche the patient is carried back to bed, where he perspires freely and reposes for about an hour.

OBSTRUCTION OF THE DUODENUM BY GALLSTONES. PREOPERATIVE LOCALIZATION; OPERATION; RECOVERY.*

By G. A. FRIEDMAN, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE YORKVILLE HOSPITAL; ASSOCIATE PHYSICIAN TO THE MT. SINAI HOSPITAL DISPENSARY.

WHILE gallstone disease is of frequent occurrence, especially in women, obstruction of the intestines by gallstones takes place much more rarely, and the diagnosis of the condition is made difficult by the different clinical pictures that may be present. In one case the only explanation of some slight intestinal disturbance of short duration is a gallstone passed in the feces; in another an obstructing stone may be palpated by rectal examination; in still another, nausea, vomiting, colicky pains and meteorism are all present.

Whenever a gallstone that has dropped into the gut cannot find its way out *per vias naturales* with or without medical treatment, while giving symptoms of its presence in the bowel, the affection becomes a surgical one, requiring early recognition and localization. While any part of the bowel may be thus obstructed, the ileocecal valve and the lower ileum are the most frequently affected, while duodenum and jejunum follow next in the order of frequency. The middle ileum, the colon, and the rectum are rarer sites of such obstruction. Early recognition is necessary because the primary irritation of the mucosa, due to the presence of the foreign body, may quickly give place to ulceration and even to perforation of the bowel, thus transforming a mere mechanical condition into one that is much more serious in regard to treatment and prognosis. The following case well illustrates the above points.

Mrs. S. M., 35 years old, a native of Austria, was first seen by me on July 9, 1907. She had suffered for ten weeks with pain in the abdomen, vomiting, and general weakness. The treatment by her family physician was of no avail, nor did the several consultants agree upon the diagnosis. Ulcer of the stomach, congestion of the liver, cancer of the liver, gallstones, and even neurasthenia were brought forward as explanations of the clinical picture. The latter diagnosis, neurasthenia, seemed most probable to the husband and he was packing his wife's trunks for a trip to the seashore when I was examining her.

She told me that she had never enjoyed very good digestion and six months ago was seized with an acute attack of illness, for which she was treated by the administration of oil and of "gallstone pills." Ten weeks ago she began to vomit, at first one to three times a day, later more frequently. The vomiting occurred in the daytime and occasionally at night, with no relation to the taking of food. The vomitus was usually yellow, and contained particles of food and mucus; on one occasion it was streaked with blood and on another was greenish. It tasted bitter, was never black and never contained "coffee grounds." The patient complained of general abdominal pain and also of pain localized in the right epigastric region. The latter was of double character: first, dull pain occurring in paroxysms of short duration, and radiating to the anterior aspect of the chest and sometimes to the left epigastric region; secondly, persistent discomfort, accompanied with peculiar sensation of contraction and relaxa-

*Read at a meeting of the Harlem Medical Association January 8, 1908.

tion in the epigastric region. The pain and the discomfort were relieved by vomiting. Her appetite was bad, especially for milk and eggs, and she suffered much from belching of gas, nausea, and waterbrash. She had lost twenty pounds in weight, felt weak, often had headache and cramps in the legs and fingers. There was no constipation, nor jaundice.

Past History.—Typhoid fever eighteen years ago. Six years ago had attacks of chills, fever, vomiting, and "stomachache," recurring at intervals of weeks and months, and was told that she had malaria. Five years ago was in bed with a similar attack accompanied by pain in the right side. Has never been free from slight pain ever since. There was no history of jaundice.

The family history was negative.

Status Præsens.—Patient middle-sized, with well-developed skeleton, flabby muscles, and reduced panniculus adiposus. The visible mucous membranes not anemic, nor icteric. Abdomen showed no distention. A small area in the right epigastric region was resistant and tender on palpation. Border of liver not palpable, spleen not enlarged, kidneys not palpable, appendicular regions not tender, rectal examination negative. Heart and lungs normal. There was no elevation of temperature. No symptoms referable to the central nervous system were present, with the exception of exaggerated knee-jerks.

We made the diagnosis of obstruction of the duodenum by gallstones, and advised that the patient be placed in a hospital for further observation with a view to early operation. Accordingly the patient was placed in the private wards of Roosevelt Hospital in charge of Dr. Joseph A. Blake, whom I wish to thank for skillfully executed operation and careful after treatment of the patient. In the hospital we proceeded to strengthen our diagnosis and obtained the following data: July 12, gastric analysis (fasting stomach); quantity expressed 60 c.c. free HCl 40, total acidity 76, combined acid 18, no lactic acid, no bile, no blood, no Boas-Oppler bacilli. July 14: Ewald's test meal, quantity expressed 60, free HCl 38, total acidity 72, loosely combined acid 16, fair starch digestion only. Blood examination: leucocytes 11,700, red blood cells 6,200,000, hemoglobin 100, color index 80. Differential blood count: polynuclear neutrophiles 65 per cent., lymphocytes 28 per cent., large mononuclears 1 per cent., eosinophiles 6 per cent. Urine was normal on admission, while on July 15 it showed strong indican reaction. The greater curvature of the stomach when inflated with air was found to lie three fingers below the umbilicus.

If we summarize the data we obtain the following picture. Data obtained from the history: (1) typhoid fever 18 years ago, (2) attacks of chills, fever, and abdominal pain six years ago, (3) fever, vomiting and pain in the right hypochondrium one year later, (4) slight but constant abdominal pain ever since, (5) absence of jaundice, (6) frequent vomiting in the last ten weeks, (7) general abdominal and epigastric pain, (8) sensation of contraction and of temporary mass in the epigastrium, (9) loss of weight, (10) cramps in the legs and fingers. Data of physical and laboratory examinations: (1) mass like resistance to the right of the epigastrium in the region of the liver, (2) position of the greater curvature of the stomach without existing dilatation, (3) absence of jaundice, (4) hyperacidity, (5) relative polycythemia, (6) strong indican reaction found once after preliminary washing of the stomach and irrigation of the bowel.

The existence of gastric ulcer was suggested, but the vomiting had no relation whatever with food, the epigastric pain was constantly present, there was no stagnation of stomach contents, and therefore no spasm of the pylorus. The absence of stagnation, the hyperacidity, the immovable mass with the absence of any cachexia spoke against the existence of cancer. Neurasthenia alone was of course not to be thought of in the presence of the above serious picture. The periodical vomiting, the resistance in the liver region, and the sensation of peristalsis felt by the patient, although we had no physical signs of it, made the diagnosis of obstruction of the bowel probable at our first examination. The absence of meteorism, the peristalsis, and the strong indican reaction spoke for the small bowel as the seat of the obstruction. As all the physical signs were in the region of the liver the bowel involved could only be the duodenum, while the absence of bile in the vomitus and in the contents of the fasting stomach placed the exact site of the trouble above the papilla of Vater.

This constructive diagnosis was corroborated by the history of attacks of pain in the right hypochondrium with vomiting, which made the diagnosis of gallstones much more probable than "malaria," especially as the patient had gone through an attack of typhoid fever some years ago. We decided that the cause of the obstruction could only be a gallstone, and diagnosed the case finally as cholelithiasis, with obstruction of the duodenum due to a calculus above the papilla of Vater. The patient was operated upon by Dr. Blake on July 15, and his report of the surgical aspect of the case follows.

Dr. Blake's Report.—Operation: cholecystectomy duodenorrhaphy, gastrojejunostomy (posterior). Incision: vertical at first through rectus sheath, oblique extension through rectus later. Pathology: the gall-bladder was crowded with small faceted stones and bound fast by adhesions to the pylorus and second portion of duodenum. Dense adhesions bound gall-bladder to posterior abdominal wall. There was an ulcerated track coated by firm adhesions from gall-bladder into duodenum. One big stone and a number of small stones were found in a pocket in the wall of the duodenum. The ulceration causing a large amount of scar tissue on outer wall of duodenum had resulted in almost complete stenosis of the same. There were no stones in the common duct; stomach showed merely distention and a fairly marked degree of gastroptosis.

The following procedure was employed: a difficult cholecystectomy was done after much dissection of the numerous adhesions which were found obliterating the normal anatomy of the structures. Duodenum was freed from gall-bladder and was found to leak slightly; it was accordingly opened at ulcerated area and several gallstones removed. The hole was closed by double Lembert suture. Peritoneal toilet: everything sponged dry and clean, and then wound incision extended down a short distance. A posterior gastroenterostomy with short loop was done by suture method. A piece of gauze tampon with rubber tissue on outer surface was then introduced into hepatorenal angle and wound approximated about it in layer sutures. Dressing: gauze, straps, cotton, bandage. Anesthesia: gas with ether. The postoperative period showed rises of temperature for a few days after the operation, highest 102.2° on the second day, traces of albumin and granular casts soon clearing up. Patient discharged August 16, cured.

TREATMENT OF EPITHELIOMA AND CARCINOMA OF THE MUCOUS MEMBRANE.

By W. D. WITHERBEE, M.D.,
CHARLOTTE, N. C.
PROFESSOR OF ELECTROTHERAPEUTICS AND SKIN DISEASES, NORTH CAROLINA MEDICAL COLLEGE.

The results of operation in this class of cases have so far been rather disappointing when compared to the same conditions existing in the skin and subcutaneous tissues. The same might be said of cancer of the tongue when it was not considered necessary to tie the lingual artery previous to the removal of the diseased area. On the other hand in cases in which the artery has been tied on the side corresponding to the part of the tongue involved, previous to the removal of the ulcer or tumor, the results have been more encouraging. Now if, instead of an epithelioma of the tongue, the case is one of the mucous membrane of the cheek or lip, and a radical operation is performed, the recurrence takes place with the same degree of certainty and the same vitality as in the case of epithelioma of the tongue when the lingual artery was not tied previous to removal.

Every operation of this kind causes a certain amount of local irritation or reaction. Irritation to any part means increased blood supply, increased blood supply means increased function; therefore, the irritation causing this increased blood supply stimulates the function of all the cells in the surrounding tissues. If in these tissues there still remain a few malignant cells hidden away in the recesses of the lymphatics they, like the rest, are stimulated. But, unlike the normal cells of the tissues, the malignant cells, being embryonic in character, not only multiply more rapidly, but increase in that one characteristic common to all malignant cells, viz., invasion and destruction of all the tissues in their path.

By far the most common example of irritation and therefore increased blood supply to the part, as the cause of increased malignancy of a slowly growing malignant ulcer, is the application of an arsenic or any caustic plaster to a rodent ulcer. Practically the same thing occurs when radium is applied to a cancer of the mucous membrane for too long a time, thereby obtaining a caustic effect similar to that of the now somewhat antiquated cancer plaster.

If, instead of simply doing a radical surgical operation and closing the exposed part by suturing the edges, the wound is left open so as to obtain free drainage and the *x*-ray is applied daily, we have what is known as "the open-method treatment," which is well adapted to the treatment of superficial malignant growths, especially in those parts of the body where the reaction or irritation does not cause the increased blood supply that naturally follows an operation on a mucous surface. Although the wound may be drained and the *x*-ray used, the increased blood supply causes such a rapid recurrence in the mucous membrane that the tumor may, in spite of drainage and the ray, persist in its growth because the superabundant blood supply to the embryonic cells remaining in the tissues in all probability causes a multiplication of new cells out of all proportion to those destroyed by the *x*-ray and drainage.

So far as the blood supply to any malignant tumor is concerned it is generally conceded that in inoperable cases the simple tying off of some of the main arteries supplying the tumor not only retards the growth but also relieves the pain and suffering until a new circulation is established.

If then, in cases of malignant growths of the mucous membrane, the operator first does a radical operation and then makes an incision through the mucous membrane well down to the basement membrane and well out from the margin of the wound, carrying this incision completely around so as to cut off the circulation of the entire area, except that from the basement membrane, he will by this means starve rather than stimulate all the cells for a short time. Having carried out this suggestion of starving the cells, whether malignant or normal, which are left after the radical operation, by means of the incision just mentioned, one can further guard against recurrence by keeping the wound open and thus obtain drainage and at the same time expose the whole part to the *x*-ray daily until the wound is healed.

Mobility of the Kidney.—At a recent meeting of the Medical Society of London, Hector Mackenzie defined a movable kidney as one in which the examiner is able to get completely above the upper end of the organ. If he is able to feel the greater part of it, but unable to get above it, it is a "palpable" kidney. In 2,801 women of all ages, Mackenzie found the kidneys "palpable" in 16 per cent. and "movable" in 18.4 per cent. In 1,067 males 2.3 per cent. had "palpable" and 1 per cent. "movable" kidneys. Kidneys are often abnormally movable without giving rise to any inconvenience, and the majority of "movable" cases require no treatment directed to that condition. The author thus describes his method: The patient lies on the couch perfectly flat on the back, the head as low as the shoulders, and the legs extended. The examiner sits on the right of the patient when examining the right side, and on the left when examining the left. The examiner first gently palpates the right side of the abdomen with the right hand from below upwards. If he finds all normal, he then places the left hand behind under the back below the last rib, and makes firm pressure upwards; the right hand is then placed flat on the abdomen in front, and palpation is made between the two hands; often the kidney can then be felt between them. The patient is at this stage asked to take a series of long deep breaths, and the lower end of the kidney will then likely be felt to descend with inspiration. In cases where there is abnormal mobility you feel the kidney descend so far that you can slip the upper border of the right hand above the upper end of the kidney. By putting forward the thumb of the left hand you can then fix the kidney in its descended position, and release the right hand, which can be employed to palpate the whole of the organ, and determine the extreme limits of its mobility. When you remove the thumb of the left hand the kidney can be felt to slip back into its position. A similar investigation is made on the left side, the hands being reversed.—*British Medical Journal.*

Pernicious Vomiting of Pregnancy.—J. Whitridge Williams declares that the treatment in a given case of vomiting in pregnancy should depend upon the variety with which one has to deal. Any existing abnormality of the generative tract or ovum should be remedied as far as possible. In the case of hydramnios or hydatidiform mole pregnancy should be promptly terminated. If the vomiting is of the toxæmic variety abortion should be induced. After the uterus has been emptied, the patient should be given abundant saline injections by the rectum or subcutaneously if the former are not well borne. The stomach should be washed out occasionally by a weak solution of sodium bicarbonate if vomiting is persistent. The patient should not be fed by mouth. Even ice should be withheld until the vomiting ceases. Reliance should be placed upon the salt infusion and enemata and the use of rectal feeding. In neurotic cases a vigorous moral lecture may prove all that is necessary. In other instances of this kind the patient should be told that her condition will not have a fatal termination. Some harmless remedy should then be given with the most minute instructions concerning the character of the food and the manner in which it should be taken. If suitable treatment is not followed by improvement within three or four days, the patient should be removed to a hospital for a rigorous rest cure. The majority of patients, however, do not demand drastic measures, but begin to improve within a week. The writer believes that the induction of abortion will become necessary less and less frequently, being reserved finally almost entirely for the cases of toxemic vomiting.—*Bulletin of the Johns Hopkins Hospital.*

MEDICAL RECORD.

New York, April 4, 1908.

TAINTED MILK SUPPLIES.

BULLETIN No. 41 of the Hygienic Laboratory of the Public Health and Marine Hospital Service, issued a few weeks ago, is a volume of much greater size and of more popular character than most of the scientific works constituting this valuable series. It has 750 pages and is on the subject of "Milk and Its Relations to the Public Health." There are twenty-one papers in the volume, written by experts, in addition to an introduction by Surgeon-General Wyman, the whole constituting a most important contribution to the vital question of public milk supplies. The investigation of which this is a report was primarily one of the milk supply of the District of Columbia, but its scope was subsequently enlarged, and the investigation was made of such a character as to be of assistance to health officers elsewhere in their struggle to prevent the wholesale poisoning by infected milk of the communities under their charge.

The conviction that is forced upon the reader of these interesting and startling reports by men who are writing, not to cause a sensation, but to state facts, is that the "jungle" as a disseminator of disease is as nothing compared with the dairy. The thought of eating meat prepared under the conditions that prevailed at one time in Chicago and that still prevail in other cities whence emanated much pharasaical condemnation of the Chicago methods, may not be pleasant, but the actual danger to health from this cause is almost negligible when we consider the morbidity and the mortality directly traceable to milk from the ordinary farm or even from many a so-called model dairy. Dr. John W. Trask of the Marine Hospital Service gives in this Bulletin a tabulated report of 500 epidemics of typhoid fever, scarlet fever, and diphtheria caused by contaminated milk. These epidemics were only a few of those which have been reported and are accessible in the literature, and how many there may have been in the past which were never reported or the origin of which was never found can only be imagined. In addition to this, a report by Dr. Anderson shows the part which infected milk plays in the dissemination of tuberculosis. He examined 272 samples of the market milk of Washington, supplied by 104 dairies, and found that 6.72 per cent. of the samples contained virulent tubercle bacilli, and of the dairies there were 11 per cent. the milk from which contained these microorganisms. One institution for children was found to be feeding its inmates on milk which caused tuberculosis in guinea pigs. Dr. Mohler's investigation led him to the conclusion that probably 25 per cent. of all the cows supplying milk to the District of Columbia are tuberculous.

The facts presented in these and the other papers included in this Bulletin only emphasize the necessity of a more thorough supervision of the sources of the milk supplies of our cities and demonstrate the present impossibility of adequate supervision when 35,000 farms and dairies contribute to the supply of a city such as New York. While recognizing the excellent work of the Milk Commission of the Medical Society of the County of New York, the requirements of which Commission are acknowledged to contain all the essential rules for the production of pure milk, the conclusion arrived at by most of the writers is that the only safety in the case of large cities lies in pasteurization. As Dr. Lumsden says, in speaking of the prevention of typhoid fever, and his remarks are applicable of course to the prevention of tuberculosis and other milk-borne diseases: "The destruction of infection in milk at the present time seems to be the cheapest and most practical method to prevent the spread of typhoid infection in the milk supply of cities. In exceptional instances when a dairy receives its supply of milk from only one or two farms over which a thorough supervision may be exercised, efforts to prevent the infection reaching the milk may be attempted. But for the general supply of cities pasteurization of the milk after it has been placed in bottles or cans for distribution is the best measure. Supplement this with an intelligent supervision over the depots and stores where milk is sold, and milk as a causative factor of typhoid fever in cities would be practically removed." Throughout the Bulletin frequent references are made to the work of Mr. Nathan Straus in the establishment of infants' milk depots for the supply of clean pasteurized milk, and Dr. Wyman, in his introduction, accords special recognition to his "philanthropic and successful efforts."

The MEDICAL RECORD has always advocated pasteurization, under official supervision, as the only practical means of prevention of milk-borne diseases in large cities. It recognizes the fact that this is not the ideal toward which sanitarians should aim, but it regards it as the only solution of the problem as yet offered. Not all the milk should be pasteurized, but only that derived from sources which are not above suspicion, which means the greater part of the milk supplied to every large city. Milk from really "model dairies" which handle only the milk from their own cows and which are inspected at frequent but irregular intervals by the health officials or the agents of voluntary commissions, such as that of the Medical Society of the County of New York, may be safely exempted from the rule of pasteurization. Such milk is undoubtedly a better food than any which has been sterilized or even pasteurized, and we would welcome any method of procuring clean milk, such for example as that described by Dr. North in the MEDICAL RECORD of February 15, which would do away with the necessity of pasteurization. But, as Dr. Rosenau says in his paper on this subject, "we must guard against enemies as long as they exist. We would all like to do away with the necessity for armies and navies, but present conditions

demand their maintenance. The same is true of harmful bacteria in milk; so long as the average market milk is apt to contain these insidious foes, the only protection we have is to destroy them with heat."

THE PERSONAL FACTOR IN DISEASE.

Sir Dyce Duckworth delivered before the Faculty of Medicine of Paris on February 18 an interesting address in which he expressed the belief that too little attention is paid in these days by the Anglo-Saxon and the Teutonic medical world to the diatheses. While acknowledging the great services rendered to medicine by means of properly prosecuted research for the sake of enduring truth and not merely to supply material for publication in journals or contributions to medical congresses and societies, he deprecated the neglect into which the old methods had fallen. It was pointed out that the teachings of the clinical laboratory are the proper study of the physician, and that far more of these are needed than are provided. As a matter of fact the clinician is always in face of the personal factor in each patient. The physiologist has an animal or some definite organ of an animal, but rarely a man before him, and consequently the problems are not the same, and never can be. Again man himself differs widely in habits or types of body; there are the arthritic, the scrofulous or lymphatic, the nervous, and the bilious, and it therefore becomes a question relating to the soil or tissue-proclivity of the particular individual that must be considered. The modern investigator occupies himself so greatly with the seed that he quite overlooks the importance of the soil.

The speaker dealt with the arthritic and scrofulous diatheses at some length, and also in relation to diet, for these conditions showed that what was meat for one disease was poison for the other. He declared that in such cases it was not only a question of microbes, but the quality of the tissues, or the soil, as well as the infecting microbe. "The proclivity, the vulnerability, the degree of immunity or resisting power is transmitted as a peculiar vital endowment from early embryonic times to full maturity in the intimate cells and tissues of the individual. In this sense each person is a law to himself, and here we have the *facteur personnel* before us with which we physicians have always to deal." The speaker dissented vigorously from the view that there is no such condition as the scrofulous diathesis, but that every individual presenting the classical features and types hitherto recognized as scrofulous is, from the earliest age, invaded and influenced by the bacilli and toxin of tubercle; in short, that what used to be known as scrofula is really tuberculosis. According to Duckworth the belief is surely bacteriology run mad and he prefers to believe that the so-called scrofulous subjects are born constitutionally feeble with a delicate lymphatic system and thus provide a favorable soil for all varieties of infection. He recognizes in the scrofulous subject the *ens in potentia* in the tuberculous subject the *ens in actu*. Sir Dyce further is of the opinion that it is possible to be scrofulous throughout life without becoming tuberculous and to be arthritically predisposed without becoming rheumatic or gouty in any classical form of these maladies. The blending of these habits of body is the outcome of heredity and tendencies passed on by each parent. Such blendings may be in variable degree according to the greater predisposition of either parent, the male characteristics more commonly reappearing in the female progeny and the female ones in the male.

After referring to what the old physicians described as the nervous diathesis, and to the sufficiently well recognized bilious habit of body, the speaker went on to say that by the light of modern clinical research into the subject of vaccine therapy, fresh knowledge may be gained in regard to the respective inherent properties of the tissues in different individuals, and we may hope in time to learn whether or not there are varying or definite powers of resistance to intruding infective agents.

The address concluded with an earnest appeal to medical men of all countries to shake off the widely spread spirit of incredulity, timidity, and hopelessness in the whole realm of therapeutics. The main business as healers and mitigators of disease was greviously neglected. Sir William Jenner said that there are but two great questions to be answered at the bedside of a sick man—what is the matter with him? and what will do him good? and therefore the progress of bacteriology could never supersede the art of therapeutics. Although this conclusion may be regarded by the Osler school of medicine as scarcely worthy of notice, yet perhaps in the breasts of the majority of medical practitioners it will find a responsive echo.

A NEW PHASE IN THE PATHOGENESIS OF INFECTION.

Recent experimental and clinical studies have thrown much light upon the series of phenomena which we term infection. The old anatomical standpoint of viewing this morbid process has given place to a dynamic interpretation and conception of the changes observed: they are now looked upon as the results of the influence exerted by two sums of living forces upon each other, those of the animal organism upon the one hand and of the infecting excitant of disease upon the other, both possessing to a high degree the power of accommodation to changed circumstances produced by such interaction. However, while this conception expresses the sum total of the phenomena of infection, its various stages are far from being thoroughly worked out; at the same time, recent observations tend to modify many of the accepted explanations that have gained currency in the earlier periods of experimental work.

Thus, in a recent article in *Russkiĭ Vratch*, Nos. 6 and 7, Vol. VII, 1908, Professor A. D. Pavlovsky of the Kieff Bacteriological Institute presents many data that throw doubt upon the usual assumption that the coverings and tissues of the animal body present an impenetrable barrier to the spread of infection while in their healthy state, the invasion of the infective agents of disease occurring only after such tissues are harmed by more or less prolonged action of the bacteria in question. As a result of numerous experiments he shows that pyogenic organisms injected into the joints of animals very quickly spread to the viscera and to the fluids of the body, this process being especially active in the first

twenty-four to forty-eight hours after the inoculation. Like experiments repeated with joints previously inflamed by the injection of alcohol and of turpentine showed marked retardation in this process, and on some occasions its total abolition. The healthy lymph-bathed tissues of the body, therefore, offer open paths to the invading bacteria, the progress of which is arrested only after the local inflammatory reaction of the tissues has had time to assert itself. Similar results were obtained with experimental infection of the pleural cavity and the use of other species of bacteria, such as typhoid bacilli, colon bacilli, etc. On several occasions after subcutaneous injections of tubercle bacilli the organisms were recovered within twenty-four hours in the urine. These results have prompted Dr. Pavlovsky to add to our conception of infection another stage, early in time and short in duration, during which the infective agents spread to the circulatory and excretory organs of the body long before the formation of manifest pathological foci. He has termed this stage in the pathogenesis of infection "the period of distribution." After this period the primary focus may no longer serve as a source of infection, and the fate of the body depends upon the relative values of its cellular and chemical defences and the virulence of the bacterial excitant of disease; either the tissues of the organism succeed in totally eliminating the invaders by way of the usual excretory channels, or succumb to them, allowing the formation of demonstrable pathological foci and thus making the infection fully manifest.

Besides the high theoretical value of these views, they are of interest in throwing light upon the clinical course of many infective diseases. Combined with the well-known possibility that bacteria may long remain latent in the body after being transported to the various organs, this phenomenon of early elimination of bacteria from a local focus of growth may give the correct explanation in many cases of so-called "cryptogenic sepsis," in which general disease of the organism is noted without any discoverable source of infection. Moreover, some of the author's results suggest that like distribution of bacteria may take place from body surfaces normally inhabited by microorganisms, in consequence of slight changes in their coverings. If this were shown further, the views of such workers as Behring, Calmette, and others in reference to the intestinal origin of tuberculosis in children would receive substantial experimental support.

The Ray Brook Sanatorium.

It is a matter for extreme regret that the trustees of the Ray Brook Sanatorium for Incipient Tuberculosis should have done anything to cause further criticism of that excellent though unfortunate institution. Friction or bad management or both have characterized its history and have raised doubts as to the wisdom of establishing it, and we can ill afford doubts now that all sanatoriums are receiving unwise opposition. It is no doubt true that home treatment can cure incipients properly situated, but there are probably more cases which should be removed from the conditions which have injured them, and places must be provided for them. It was hoped that by placing the employees at Ray Brook under the civil service law, it would be possible to prevent the personal or political favoritism which has been the bane of other State sanatoriums from which splendid men have been summarily discharged to the injury of efficiency. It is now said that the Civil Service Commission is not able to select a competent superintendent and that the trustees have determined to evade the law and appoint a man whom they consider better than any other applicant, even going to the extent of changing the law to make their selection eligible to compete. Of course it is evident that they are doing what they think is best for the welfare of the institution, but it is to be remembered that a certain warm place is paved with good intentions. That is, a desire to do right in a wrong way does more harm than good, and the end does not always justify the means. In this case it is deplorable that they did not decide to abide by the strict letter of the law, for the impression has been gained by many that the examination for superintendent was disingenuous and a mere matter of form. There is some truth in the claim that the trustees are better able to judge of qualifications than an alien commission, but it is a system which has given rise to such abuses that publicists have almost universally condemned it and are advocating an extension of civil service methods. Should they succeed in overriding the law, then it will be but a step to discharge employees who have incurred personal enmities, and the friction will continue indefinitely. Better by far to take a man who has proved his fitness for the place, so far at least as professional qualifications are concerned, even though the trustees may not consider him the best possible choice, than to have run the risk of the present unpleasantness which may indeed have far-reaching consequences.

The Overcrowding in the New York State Hospitals for the Insane.

This is a theme which has attracted attention and consideration many times during the last five years. The certification of most of the State hospitals for the insane is fictitious and is overstated at least six hundred beds in a total capacity of 23,525 beds in the thirteen hospitals. The number of patients in the hospitals at times has been over two thousand in excess of this fictitious capacity. The overcrowding is due entirely to the increase in the insane population of the Metropolitan district. With the exception of the hospitals at Buffalo and Utica, no hospital north of New York City can be filled without making transfers from Manhattan. In other words, the nine hospitals north of New York City can more than take care of themselves, and would have many empty beds were it not for the teeming insane population of the Greater City of New York. The hospitals at Kings Park, Central Islip, Flatbush, and Wards Island, New York City, are overcrowded to an extreme degree and no relief can be found until a new hospital is erected in the southeastern part of the State. A bill was passed by the legislature of last year directing the State Commission in Lunacy to obtain a site in this part of the State for such a hospital, and the Governor in his annual message strongly urged that this be done. A bill was introduced in each house of the Legislature last week providing for an appropriation of $119,250 for the purchase of a site comprising 408 acres at Congers, Rockland County, New York. This site offers remarkable advantages and is in almost all respects ideal. This bill will undoubtedly become a law promptly and the Commission will be empowered to commence at once the erection of an institution with a capacity of 2,500 or 3,000 inmates.

The Transplantation of Formaldehyde-fixed Blood-Vessels.

The striking and epoch-making experiments of Carrel have opened up a new field of surgical endeavor, the far-reaching results of which are hardly appreciated by the casual observer. The demonstration of the successful suture of blood-vessels has brought within the range of possibility, if not immediate probability, not only the cure of aneurysm by extirpation of the dilated portion of the vessel and its replacement by a segment of a vessel from one of the lower animals or by a diversion of the blood stream through a neighboring artery or vein, but even the transplantation of an entire organ to serve in the place of one rendered useless by disease. A recent experiment of Dr. C. C. Guthrie of St. Louis, reported in *Science* of March 20, has shown that it is not even necessary to use a fresh vessel for successful implantation. He removed a segment of the vena cava of a dog and kept it in a 2.5 per cent. formalin solution (in 0.9 per cent. sodium chloride solution) for sixty days. He then cut a segment 0.75 cm. in length from the common carotid of another dog and filled the gap with this formalin-fixed vena cava. Three weeks later he examined the artery and found the segment in place, somewhat elongated and of smaller diameter; it pulsated strongly and the circulation through it was perfect. Before being sutured to the artery, the vein was removed from the formalin solution, washed in dilute ammonia, dehydrated in absolute alcohol, and impregnated with paraffin oil.

Rectal and Axillary Temperatures.

That the difference between the temperature of the axilla and of the rectum is likely to be considerable in cases of fever is well known, and on this account it has come to be an accepted rule that whenever an accurate temperature record is of importance the determination shall be made by rectum. Some surgeons, such as Madelung and Lennander, have asserted that in cases of suppurative peritonitis the customary difference between the temperatures obtained in these two ways was increased, sometimes amounting, according to the former, to as much as 2.7° F., and that this fact might be made use of in diagnosis. Other observers have contested this view and have suggested that the differences noted were probably due to the fact that it is difficult with restless patients to obtain reliable axillary readings. This matter has been made the subject of investigation by Propping (*Münchener medizinische Wochenshrift*, March 10, 1908), who, as the result of observations on himself under varying conditions, and on a number of patients suffering from febrile disorders, reaches the conclusion that both in sickness and in health the amount of difference depends on the condition of the axilla, and when the disparity is great this is the result of an abnormally low axillary temperature, being inversely proportional to the activity of heat formation in the muscles. Large differences, *i.e.* of more than 1° C., occur not only in peritonitis, but also in other febrile diseases. When observed in peritonitis the symptom indicates a severe infection and is therefore a sign of grave omen. While the practical value of such evidence is perhaps not very great, as there are usually other indications of more importance, Propping's studies serve to emphasize the necessity for resorting to the more troublesome and disagreeable method of temperature determination in all cases whenever anything more than a slight indisposition is in question, and always when the diagnosis is uncertain.

A Cutaneous Reaction with Diphtheria Toxin.

While the practical value of the new tuberculin reactions by cutaneous inoculation and instillation into the conjunctival sac is still undetermined, it is evident that the field opened up in this direction is a wide one that promises to facilitate further advances in the intricate subject of immunity and the defences against disease. Some of the possibilities of this nature are hinted at by Schick, who has been investigating the effect of making cutaneous inoculations with diphtheria toxin. In a paper in the *Münchener medizinische Wochenschrift* of March 10, 1908, he says it is possible to obtain in this way reactions perfectly similar to the cutaneous tuberculin lesions, though the test is not a specific one, since a large proportion of healthy infants and older children give a positive result. Various theoretical considerations lead Schick to believe, however, that the procedure may be used to advantage in other ways, for example, for the investigation of the clinical aspects of the disease and also as a means of testing the strength of diphtheria toxin without having recourse to the roundabout and not altogether satisfactory method of animal inoculation.

News of the Week.

Site for the New Custodial Asylum.—At the meeting of the Medical Society of the County of New York held on March 23 a resolution was adopted urging the members of the society to support Senate bill No. 636 and Assembly bill No. 1215, which provide for an appropriation of $188,575, for the purchase of a site for a new Eastern New York State Custodial Asylum near Haverstraw, Rockland County. It is represented that the existing State Custodial Institutions, located at Rome, Syracuse, Newark, and Sonyea are overcrowded, so that a new asylum is urgently needed, while the site proposed is not expensive and has the advantage of accessibility from New York City.

Progress in the Sanitation of the Philippines.—In an editorial appearing in the *Manila Times*, January 30, 1908, Dr. Victor G. Heiser, Director of Health, is credited with having been largely instrumental in the great improvement that recent years have seen in health conditions in the islands. Among the benefits enumerated are the following: The high percentage of cholera cases saved, the entire eradication of smallpox in many provinces that used to pay their toll of hundreds of thousands annually, the improvement in surgical statistics, the practical extirpation of bubonic plague, the reduction of infant mortality, the pronounced decrease in general mortality, and the vaccination of millions.

Health Commission for Lake Michigan.—Health Commissioner Dr. William A. Evans of Chicago has suggested that a commission be created representing the cities on or near Lake Michigan, their states, and the federal government, to study and report on the present use and future possibilities of the lake as a reservoir for both water supply and sewage disposal. The formulation of his plan is in part a result of cooperative work being carried on by the various health officers forming the Chicago and Suburban Health League. Through discussions at its meetings it has been concluded that the existence of typhoid fever in this vicinity is traceable to the large amount of sewage emptied into the lake. Dr. Evans' plan provides for the appointment of members of the commission by the mayors of Chicago, Milwaukee, Grand Rapids, Hammond, Whiting, and East Chicago, and by the governors of

Illinois, Wisconsin, Michigan, and Indiana. Two members, representing respectively the War Department and the Marine Hospital Service of the National Government, are also suggested. Mayor Busse of Chicago is expected to submit this matter to the council soon.

XVI International Medical Congress.—Professor Emil Grosz of Budapest, secretary-general of the sixteenth international medical congress, which is to be held in Budapest, August 29 to September 4, 1909, has sent out the preliminary program of the congress. There will be twenty-one sections and a considerable list of papers has already been pledged. The president of the National Committee for the United States is Professor J. H. Musser of Philadelphia. The secretarial office of the congress is Esterházy-Utcza 7, Budapest VIII, Hungary.

Results from Free Antitoxin. According to a report issued by the Pennsylvania State Department of Health 4,693 cases of diphtheria among the poor were treated during the year 1907 with free antitoxin, with 371 deaths, a percentage of 7.9 as against a percentage of 11.13 in the year 1906. It is estimated that this represents a saving of 1,506 lives. In addition immunizing doses of antitoxin were administered to 3,015 persons, of whom only 34 contracted diphtheria, and of these only 2 died. These results have been accomplished through the establishment of numerous distributing centers in convenient parts of the State, from which antitoxin can be obtained without expense by families certified by attending physicians as too poor to pay.

International Trachoma Prize.—The Royal Hungarian Minister of the Interior offers the sum of 1,000 crowns as a prize to the author of the best work on the etiology of trachoma. All essays, whether in manuscript or published for the first time in 1907 or 1908, will be eligible for the competition, provided they are in English, Hungarian, French, or German, and that they are received on or before December 31, 1908, by the Minister of the Interior. Address: Belügyministerium, Budapest, Hungary. The jury will be appointed by the minister, and the winner will be announced at the inaugural session of the sixteenth International Medical Congress to be held in Budapest, August 29 to September 4, 1909.

Philadelphia Municipal Appointments.—Dr. S. S. Woody has been appointed chief resident physician at the Municipal Hospital of Philadelphia, in succession to Dr. B. F. Royer, resigned. Dr. Edward K. Mitchell has been appointed third assistant resident physician on the non-salaried staff at the Municipal Hospital to succeed Dr. Chas. J. Swlam, promoted to second assistant resident physician. Dr. Henry J. E. Newman has been appointed registrar to the Philadelphia General Hospital, in succession to Dr. Charles M. Montgomery, resigned.

A Banquet in Honor of Koch.—A banquet at which Professor Robert Koch is to be the guest of honor will be given under the auspices of the German Medical Society at the Hotel Waldorf-Astoria on April 11. Dinner cards can be obtained from Dr. Geo. Mannheimer, 60 East Fifty-eighth street. The price is $7, including wine.

The Middleton Goldsmith Lecture of the New York Pathological Society will be delivered by Professor Frank B. Mallory, of Harvard University, at the New York Academy of Medicine, on April 4, 1908, at 8:30 P.M. The subject will be "The Results of the Application of Special Histological Methods to the Study of Tumors." The lecture will be illustrated and all interested in the subject are invited to attend.

Medical Society of the Missouri Valley.—The semi-annual meeting of this association was held in Lincoln, Neb., March 19-20, under the presidency of Dr. W. F. Milroy of Omaha. The address in medicine was delivered by Dr. C. H. Hughes of St. Louis.

The American Society of Sanitary and Moral Prophylaxis.—A meeting of this society will be held at the Academy of Medicine on April 9, at 8:30 P.M. Papers on the Social Evil will be read by Dr. S. A. Knopf and Mr. Frank Moss.

American Proctologic Society.—The tenth annual meeting of this society will be held in Chicago June 1 and 2, 1908, under the presidency of Dr. A. Bennett Cooke of Nashville, Tenn. The secretary is Dr. Lewis H. Adler, Jr., of Philadelphia.

Confederate Army Surgeons.—A reunion of the surgeons who served in the Confederate army or navy is to be held in Birmingham, Ala., in June, under the auspices of the Jefferson County Medical Society.

International Congress of Thalassotherapy.—The fourth International Congress of Thalassotherapy is to be held in Abbazia on September 28, 29, and 30. The general secretary is Dr. A. Oliven, Berlin.

Dorchester Medical Society.—An organization with this title was formed in Dorchester, Mass., on March 25 with the following officers: *President,* Dr. Madison T. Thurber; *Vice-President,* Dr. Robert M. Merrick; *Secretary and Treasurer,* Dr. H. F. R. Watts.

Abilene County (Kan.) Medical Society.—At the meeting of this society held in Abilene on March 17 the following officers were elected: *President,* Dr. P. B. Witmer; *Vice-President,* Dr. S. S. Steelsmith; *Secretary,* Dr. S. Nichols; *Treasurer,* Dr. Klingberg.

Tenth Councilor District (Ark.) Medical Society.—At the meeting of this society, held in Fort Smith on March 20 officers were elected as follows: *President,* Dr. G. F. Hynes of Fort Smith; *Vice-President,* Dr. Young of Springdale; *Secretary,* Dr. D. R. Dorente of Fort Smith; *Treasurer,* Dr. Bourland of Van Buren.

Medical Inspection of Schools.—The medical inspectors of schools of Chicago examined 6,887 pupils during the week ended March 21, and excluded a total of 217 on account of contagious diseases. The principal causes of exclusion were as follows: Chicken-pox, 41; measles, 41; whooping cough, 6; mumps, 4; scarlet fever, 9, and diphtheria, 1. School children to the number of 827 were vaccinated by the inspectors.

Stony Wold Sanatorium. The sum of $1,200 was realized at a bridge tournament held last week at the St. Regis for the benefit of this institution.

Christian Science Death in Chicago.—The Chicago Board of Health is investigating the death of the wife of a naval officer who died under Christian Science treatment after an illness of thirty days without medical care.

Yacht Quarantined.—Owing to the presence on board of two sailors ill with symptoms not unlike those of plague the steam yacht *Wakiva* from South American ports was fumigated and kept in quarantine pending bacteriological examinations by the Health Board.

Plague in Ecuador and Venezuela.—Numerous cases of plague are being reported from Guayaquil

and La Guayra and a quarantine against these places is being enforced in the canal zone.

Against the Antivivisection Bills.—A considerable delegation of medical men, comprising some of the best known members of the profession in this city, went to Albany last Wednesday to protest before the joint Judiciary Committees of the Senate and Assembly against the antivisection bills under consideration.

College Closed Owing to Diphtheria.—As the result of an epidemic of diphtheria, Concordia College, at Hawthorne, in the northern section of Westchester County, has been closed, and the eighty students have been sent to their homes.

New York Infant Asylum.—Plans have been filed for enlarging the four-story building of the New York Infant Asylum, at the corner of Amsterdam avenue and Sixty-first street, by the addition of three new stories, at a cost of $30,000.

Vacancies in Genitourinary Dispensary.—There art two vacancies at the Genitourinary Clinic of the West Side German Dispensary, Tuesday, Thursday and Saturday evenings, 7:30 to 8:30. Applicants may communicate with Dr. Abr. L. Wolbarst, 105 East Nineteenth street.

Obituary Notes.—Dr. John A. McIlwain of Mount Tabor, Or., died on March 18 at the age of thirty-eight years. He was graduated from the University of Pennsylvania Medical School in 1891 and practised for a time in Kansas City, Mo. He had been a resident of Mount Tabor for about three years.

Dr. Herbert O. Pease of Springfield, Mass., died on March 23 at the age of fifty-two years. He was a native of Monson and was a graduate of Dartmouth, receiving his medical degree from the New York University Medical School in 1882, since which time he had practised in Springfield.

Dr. Robert F. Burleigh of South Braintree, Mass., died on March 22 at the age of forty-six years. He was a native of New Hampshire, but had practised in Braintree for about ten years, and was a member of the Board of Health of that place.

Dr. Anne A. Wilson of Washington, D. C., died on March 14 of diabetes at the age of fifty-one years. She was a native of Baltimore, and received her medical education in several European universities. In 1894 she returned to this country and began practice in Washington, where she held a prominent position in medical and social circles.

Dr. John Bryant of Boston, Mass., died on March 20 at the age of forty-seven years. He was born in Boston, the son of Dr. Henry Bryant, and was graduated from Harvard in 1873, receiving his medical degree from the Harvard Medical School five years later. Dr. Bryant devoted his life and professional activities largely to charity and philanthropical work, and accomplished much in alleviating the condition of the working classes. He was an enthusiastic yachtsman and took part in a number of the America Cup races.

Dr. D. M. Finley of Cascade, Ia., died on March 16 at the age of sixty-nine years. He served through the Civil War, and then began the practice of medicine in Canton, Ia. About thirty years ago he removed to Cascade.

Dr. George F. Butman of Somerville, Mass., died on March 22 at the age of seventy-one years. He was born in Boston and was graduated from Harvard Medical School in 1864. He practised in Wrentham until fourteen years ago, when he retired and removed to Somerville.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth concisely the nature of the ailments therein described with remarks on their appropriate treatment.

——————— Indiana.

Dear Doctor:

I met at the shore this summer one of your patients, who told me how much relief she had got from following the plan of treatment you outlined for her in New York last winter. She made me promise that I would write to you and describe my symptoms and ask you whether or not I may look forward to any relief from the suffering which for twenty years I have borne with little fortitude.

When I was fifteen years old, parenthetically, I am now 37, happily married and blessed with three children, I began to have headache. Periodically since then, first once a month, later every two weeks, I have had attacks. I was nearly 14 years old when I first menstruated. When I have a headache at the time of my period it is more intolerable, but aside from this I have never been able to satisfy myself that there is any relationship between them. They have so overwhelmed me that I am "out of commission" for nearly a week. The first two or three days from the pain and then another day from the prostration which now always follows. When the headache first came the pain was located between the right eye and the temple. From there it would gradually spread over the right side of the head and sometimes extend even to the other side. The truth is, that after the pain has been present for a few hours I am so miserable and unable to give thought to anything save to the struggle to live through the attack, that I can't say just where the pain is or is not. When the attacks are severe they are apt to be preceded by nausea and vomiting. This occurs less frequently now than formerly. Sometimes, also, before an attack, I experience an indefinable sadness and depression not attributable to anything in my surroundings, which occasionally lasts as long as two or three days. At other times before the attack I experience a very peculiar disturbance of sight. I am not sure that it should be so described, for the sight does not seem to be really affected. What occurs is that just before the pain sets in or, simultaneously, there seems to be a small black spot which floats around in my field of vision. Every time I move my eyes it moves too. At times when the pain in the head comes on with unusual severity and rapidity this black dot seems to be transformed into a small ball of light. On a very few occasions this light seems to have had a zig-zag movement. Lately I have had, in addition to headache, a great deal of trouble with digestion, gas forms in the stomach and intestines, and I think that it must be that that causes so many queer sensations in my abdomen, fluttering, distention, sometimes so great as to necessitate removal of stays and loosening of waistbands. I have also got very much run down and nervous. I cannot do the things socially or in my family that I could a few years ago, for if I do I am so used up that I am sure to get a headache. Perhaps I have said enough to give you an idea of my case, but I must tell you what has been done for me, or rather, how I have been done by your confrères.

It is a long story, longer even than that which I have written about myself. When I first had headaches my mother took me to our family doctor, who gave me a new medicine every time I went to him and who finally acknowledged he could not help

me. He consoled me, however, by saying that I would grow out of them, and on one occasion I overheard him tell my mother that they would probably disappear after I married. I won't say that I accepted the first man that proposed because of this knowledge, but when I did accept one he was lacking the magical possession that was to cure me. I had fewer headaches the first two years after I was married than before, but after the baby was born they came with the old time frequency, and I took a great many medicines, but without relief. Then the doctor discovered that I had a slight tear of the neck of the womb, from which he said the headaches were reflex, so I was curetted and repaired. But I had headache just the same after I got about. The next year I was sent to Chicago to have my eyes looked after and the doctor there was sure that my headaches came from astigmatism and "improper implantation" (those were the terms he used, so I thought I was a speciment though now I know I was a farm—and he a "farmer") of the muscles, so he decided to plant them over. He did. I was sorry for myself, and I have not got over it yet.

About a year later one of your New York men, an individual with a manner, a white waistcoat and an oracular way of being laconic, came out to read a paper before the doctors here. He seemed to have brought his tools with him, for he operated upon three of my sex the day after he arrived, and the day following upon me. I had floating kidneys, he said, and they should be anchored. I had been planted, now I must be anchored. I couldn't understand how floating kidneys caused headaches once or twice a month and not at other times, but then the trouble was with me in more senses than one. I shall make no further comment than to say that I am sorry that he came out here to read that paper.

About this time Dr. ——— settled here. No one knew much about him except that he had practiced in Chicago and had been extremely successful there, but the climate did not agree with his wife and he decided to throw off the hold his practice had upon him and devote his life to his wife. This seemed to leave him time to devote himself to practice here, for within a month after he came he was doing nearly all of it. I am no better than my neighbors; I had him. At last I seemed to have found a pillar of strength and a tower of wisdom to tie up to. He was sympathetic and understanding, and he had seen hundreds of such cases among the best families on Prairie avenue, and although it was not a patency of good form to have such headaches in Chicago, they were much more common in the first families than in the newcomers. Such headaches come from the liver. They are dependent upon "insufficient metabolism"—a process which is carried on in the liver. In my case the procedure was insufficient because the capsule of the liver had stuck to that organ in the same way as a veil sticks to your face (our faces I mean) when it becomes wet. I learned to talk the lingo and I was only sorry that I couldn't be present save in the spirit when he shook the sistrum and lifted the veil from the goddess of metabolism. I was ill in bed a long time after this. I don't know just what they did to me then, but the doctor said it was a capital operation. At times he used language loosely, very much as he did my anatomy.

I then decided to give up doctors and bear my cross as best I might. I had whiled away some of the weary hours while convalescing from the last operation by reading the "Power of Silence," and I decided to fill my mind with love, the world beautiful, an abstract God and other pain-preventers and misery-mitigators, and it worked splendidly until the first real headache came, then my idolized trinity was a flash in the pan and there was scarcely a memory of them left. After that a friend of mine, a lady who had been cured of cancer after having been given up by all the doctors, came to see me and told me of her own miraculous delivery and of scores of others, so I was prevailed upon to send for the wonder-worker. He told me that my spine was dislocated and from that the headaches flowed. I can't imagine how he knew this, for he didn't look at my spine or make any examination whatsoever, but he could cure me, he said, in about forty treatments, and as that is what I was searching for, the promise of it even was better than nothing. My spine was an obstinate one and forty interviews only served for a bowing acquaintance, so I took forty more; then I suddenly felt poor in purse and proud in person and decided to give it up. As a matter of fact, I felt better generally after this treatment than I had for some time, but it had no particular effect upon the headaches.

These latter experiences, while causing me to lose faith in the supernatural, did not restore that restful and supreme confidence which I once had in the educated, level-headed members of your profession and which I wish I might have again. I resolved firmly to have no more opinions from doctor or priest concerning the nature of my ailment nor to solicit expressions of opinion as to the course to be adopted to cure it. I need scarcely tell you that this resolution was made in an interval during which I was freer from attacks than usual.

My good intentions (perhaps you will not appreciate my adjective) fell before the demon Pain and I was glad to consult a physician in Cincinnati who had been recommended to my husband. I went to see him and spent a week at a hotel there while he was completing the examinations, which were made with much thoroughness so far as I, a laywoman, could judge. He gave me a test breakfast, then pumped it out and analyzed it. I had too much acid. Heretofore my doctors had found me deficient in things (*they* were lacking in what I considered to be one essential, I thought) so this was quite encouraging to me. Then I had to swallow a ball as large as a marble, of lampblack, which I was assured was inert and then weigh all the food I ate for a certain period, then swallow some more lampblack. I got quite interested in this. Then there were a lot of other examinations to determine my "metabolic coefficient" and my "elimination capacity" and things which I never knew any human being, let alone a woman, had. At last it was decided that the trouble with me was that I was the director of a large manufacturing plant situated in "our midst" engaged in making poison. I was the sole consumer and of course the monopoly wasn't good for me; in fact it gave me headaches. This was a most plausible and alluring explanation, at least so much of it as I was able to understand. I didn't fancy myself very much when I let my mind turn to my occupation, but in reality I didn't have much time to think about anything save the stunts I was obliged to do to get well. I had a green vegetable diet. The word green or the sight of green calls up memories that I would gladly be without. The sight of spinach has the same effect upon me that the odor of garlic, consumed the night before, has upon most people. And so far as baked apples are concerned, well, if it hadn't been that an apple and Newton were responsible for gravitation, I could wish the

apple had never been born. I suppose I must tell you of the "irrigation" too, though I should prefer not to do so. When I hear the word irrigation I have the shivers. When I read of how the deserts of Texas and Utah have been reclaimed and converted into fertile valleys laden with tropical vegetation, blossoms and fruit which rival in their appearance the panorama once seen by mortal eye from the summit of Mt. Pisgah, a silent prayer is registered that irrigation will soon be reserved for such purposes and not applied to the human anatomy. All this time I took disinfectants until I was convinced that my interior was no better than a pest house.

Oh, well, why burden you with more of this, you know I didn't get well. Had it been otherwise I should not be consulting you. Sir Leslie Stephen, in his delightful "Hours in a Library," says everyone should write an autobiography, first, because human documents are always interesting, and second, to explain, if possible, how one can be so dull. I am not aiming for either of them. My inquiry is a simple one. Can I be relieved or must I go on suffering these occasional torments until I am translated? I don't care a fig about the name of the disease, that geniuses have had it, or that it accompanies usually a high order of intellectual or emotional endowment. I know it, your colleagues have told it to me, and it doesn't help me a bit. What I want to know is, what shall I do to be saved, and I cry out with the anxiety and agony of a penitent sinner who sees the traditional hell being adapted for the conveniences of his immediate occupancy.

Yours respectfully,

New York, Feb. 24, 1908.

Dear Madam:

You have had an unfortunate and, I hope, uncommon experience with the guild of which I am a member. Headache is a very common affliction. It has been stated that one person in five is subject to it. This alone indicates that it is the expression of many different diseases and disorders, most of which are curable. For instance, nothing is more firmly established in our art than that headache is often dependent upon defects of the sight apparatus, causing what is called eyestrain. That is why so many patients with headache are benefitted by the ministrations of an oculist. What I wish to convey is, that headache is nearly always the symptom of some disordered condition of the body, and that this disordered condition can usually be relieved, but in your case headache is a disease.

The disorder from which you suffer and which you have described so fully is known to physicians as migraine and to the laity as sick headache. The headache and other symptoms that you have more or less periodically is merely the expression of a disorder which you have all the time. This may be difficult for you to believe when you reflect that you are in excellent health and corresponding spirits in the interval between the attacks, but no one doubts that the unfortunate victim of epilepsy is still the victim of the disease even though his attacks be separated by intervals of many months. In other words, migraine is a constitutional disorder, the symptoms of which occur occasionally. We physicians speak of it as a nervous disorder of degeneracy or deviation. By thus designating it we endeavor to indicate that it occurs in individuals whose evolutionary development has not been sufficiently harmonious to allow the different components of the finished product to so work in unison that the result is a symphony, emotional, intellectual or physical. Such a condition is a defect of heredity and if you will search your ancestry you will find that someone from whom you are directly descended, very likely your mother or grandmother, was similarly afflicted or had some oddity of her mental, emotional or physical makeup that distinguished her from other people. You will gather from this that I lay great stress upon heredity as a potent factor in the causation of so-called functional nervous diseases. Men and women learned in the laws of heredity, and professional biologists tell us of many things in our moral and physical makeup that is the result of reaction to environment, but one cannot have been a neurologist for twenty-five years without having been led to the conclusion that it is heredity, and not environment that contributes materially to his clientele.

All this is very interesting you may say, but what bearing has it upon the cure of your headache? A very great deal, I assure you. If you can gain a conception of the nature of your ailment and the way in which it developed, then you will not be overwhelmingly disappointed when I tell you that the profession of which I am a member is powerless to cure it. We are able to suggest to you certain reforms in your mode of life, in your conduct, in your habits, etc., which, if instituted, will be followed by very great relief. Not infrequently we are able, by correction of certain structural faults of the different sense organs, such as the eyes, nose, ears, etc., to very materially diminish the number of attacks, but we are not able to cure the disorder any more than we are able to give a harmonious blend to the hirsute appendages of the gentleman who has black hair and red beard, or who has one blue and one green eye, or to overcome long prehensile index-fingers, to do away with other signs of disharmonious evolutionary development.

Headache, you know, may be caused by indigestion and constipation, which may be relieved by taking calomel or other aperient. Headache often comes to those who do not eliminate adequately through the skin and through the kidneys, and headaches occur frequently in individuals whose eyesight is poor and who have other abnormalities of their visual apparatus. Headaches occur in persons who have obstruction of the nasal passages and of the hearing passages, and headaches occur in individuals who are "run down" and exhausted from innumerable causes. I should not particularize them did I not wish to say that these organs are oftentimes a little off the key, as it were, in individuals who manifest that sign of disharmonious development known as migraine, which you have. Therefore, one of the first things that a migrainous individual must learn about himself is, what manifestations of departure from the normal has he in any of these organs, and how completely can such abnormalities be overcome? The migrainous individual who accomplishes this and who looks after his digestive apparatus and his avenues of elimination, who avoids over-fatigue, who maintains a high degree of bodily health (which, by the way, I hold is inconsistent with the habitual use of stimulants and the modern habit of excessive meat eating), will have headaches very rarely and when it does occur it will probably be not very severe.

I hear you say that to accomplish this you must become a self-centered, self-watchful individual. I do not admit it. One of the first things that every individual must learn is his or her limitations. The more closely he safeguards them the

less often and severely will he be injured. If a sensitive person goes about saying disagreeable things about everyone he sees or knows, sooner or later he is sure to hear similar things said about him. The sensitive person should acquire the habit of praising or he should get tongue-tied. Neither one will subtract from his moral or intellectual stature. On the contrary, they will contribute to his happiness. In this same way you will materially smooth your path and lighten your burden by adopting a practically vegetarian diet, while walling up every avenue that leads to useless exhaustion of your energy.

Make a careful inventory of the things you do in the name of pleasure or diversion, and find out how many of them give you real thrills comparable to that which you felt when your husband, then courting you, first read to you those verses beginning:

> There's a woman like a dew drop.
> She is fairer than the fairest.

and with all your intellectual and emotional soul you thought he meant you; or anything approximating the divine strength and resistance you felt march majestically into your soul on conquering some mean and ignoble temptation, or the upilft that you have had from listening to inspiring music, or the peaceful serenity and contentment that has come from the growth of family feeling. You will find, I think, that most of the things that you do in the name of pleasure are stupid, inane, boring, stultefying and profitless. I advise you to cut them out, they contribute to migrainous attacks! In the same way scan carefully the incidents of daily life that exhaust you. You will find that most of them are purposeless and can be avoided without curtailing your activity or your efficiency. Ask yourself seriously the purpose of life, and having answered it bend yourself to the realization of it joyously. You will find that it is not exhausting, it is exhilarating. It goes without saying that if you find the purpose of life is to be harassed by the problem of domestics, to devise means of suppressing vivisection, or to win the first prize in a transcontinental bridge whist tournament, you are likely to be disappointed with existence here below, and also to have many headaches. On the other hand, if you see your way clear to devote your life to making this world a most attractive tarrying place for your husband, children and neighbors, en route to Heaven, you will find that serenity and contentment which the sage in meditation found, and with it health and happiness. Moreover, you will find that such conduct is an anodyne in hours of suffering, a stimulant in hours of weariness and an added joy to life at other times.

"But," I hear you say, "am I to take no medicine?" Yes, dear madam, you are to take ten grains of gray powder every 21 days on retiring, and in the morning take a mild saline laxative like sulphate of magnesia. Gradually as your headaches get less frequent, make the interval between such doses longer. This may soon be accomplished if you will so arrange your diet, your exercise and your habits, that you get a copious and adequate evacuation of your bowels each day—for that which we call "hepatic inadequacy" is a powerful force in causing attacks of migraine.

When your headaches are very severe, send for any good common-sense doctor, and ask him to give you one or two doses of some simple pain reliever. Tell him you don't want to be cured, you want only to be relieved. Smile blandly at the doctor who says he can cure you.

Yours sincerely, ——.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INFECTIONS OF THE URINARY TRACT—ULCERATIVE COLITIS OR DYSENTERY?—COLLEGE OF SURGEONS' LECTURES—INTERNATIONAL CONFERENCE ON SLEEPING SICKNESS—WHISKEY—GRANT FOR RESEARCH—DIARRHEA AND FLIES—OFFENCE UNDER THE HUMAN LAWS—OBITUARY.

London, March 13, 1908.

The Erasmus Wilson lecture for this year was delivered at the Royal College of Surgeons on February 14 by Mr. Leonard S. Dudgeon, who took as his subject "The Acute and Chronic Infections of the Urinary Tract Due to the Bacillus Coli." He discussed the clinical and bacteriological points at length, but perhaps his most interesting statements relate to treatment. Apart from infections due to the *B. coli*, those due to other causes are often rapidly improved by drugs. The success from urotropin is phenomenal, especially in *B. typhosus* infections. But when the *B. coli* is the cause the lecturer's experience gave no encouragement. Most of the cases he had investigated had been previously treated with almost every known drug without benefit. To account for reported cases he suggested that they had not really been due to the *B. coli*, in the diagnosis of which there was great lack of method, or else that the condition was only relieved, not cured, or that treatment was begun just as spontaneous recovery was about to occur. It is well known, too, that infections due to *B. proteus* rapidly yield to antiseptics and washing the bladder, but the lecturer had seen no beneficial effect from this when the *B. coli* was present.

Treatment by anti-colon bacillus serum has been tried in over fifty cases, twelve by the lecturer himself. In five of these he found the effects rapid and permanent, no return having occurred so far as he knew. In four cases considerable benefit ensued: in two only slight improvement; in one, which was the least acute, the joint pains and rashes produced by the serum seemed almost worse than the disease. No doubt some people possess an idiosyncrasy for horse serum, but this is not recognizable until the remedy is injected. Calcium lactate, 20 grs. t.d., was advised at the time of using the serum, as in many instances it had mitigated the objectionable effects. In subacute cases the lecturer pronounced serum to be decidedly useful, though much less so than in the severer type. In chronic cases it occasionally may do good, though probably the apparent effect is a mere coincidence and usually, Mr. Dudgeon said, it was absolutely useless. It seemed best in acute and to a less extent in subacute cases. His experience indicated 25 cubic centimeters each day for three days. If no effect was produced, it should be discontinued, lest complications follow.

Vaccine treatment does not give such satisfactory results in cases due to *B. coli* as in cases of *Staphylococcus aureus* and *albus*. After treating many cases, the lecturer could not report material improvement except in a few instances, though some patients felt better, but he disregarded that if the urine remained in the same condition as at first. Moreover, he thought improvement as estimated by the opsonic index could give little satisfaction to either patient or doctor so long as the urine remained unsatisfactory. Further, chronic cases have a great tendency to relapse, and that, too, with extraordinary suddenness. This is a most important fact to remember, as cases supposed to be cured may pass into other hands with the urine turbid from *B. coli*. The lecturer had seen a case in which the urine had become quite clear and no bacilli could be found even after centrifugalization, but on addition of large quantities of that urine to culture media growth of *B. coli* was obtained. As to the question who should be treated by vaccine and who should be left to nature's efforts, Mr. Dudgeon said, it is certain that every chronic case is liable to acute attacks which are often of the greatest severity. On the other hand, there are many people who have never had any definite symptoms necessitating medical aid, although the urine has been known to be turbid for a long time, and there are also many whose urine is infected unknown to themselves or their medical advisers. There is therefore considerable difficulty in settling the question. But "if definite treatment is decided upon in chronic infections of the urinary tract due to *Bacillus coli*, the vaccine treatment should be adopted, employing the organism isolated from the patient's urine."

What is colitis? The question of one form at least

was raised at the Medical Section of the Royal Medical Society, apropos of a case described by Dr. Sidney Phillips, which, although associated with some unusual symptoms, he diagnosed as "acute ulcerative colitis." The patient was a house painter and his illness was at first considered lead colic. But on the third day he went to the hospital with profuse diarrhea, pain, and some pyrexia. On the seventh day anuria appeared, and he said on the ninth, at the autopsy, the whole length of the colon was found to be acutely inflamed with general denudation of the epithelium and small early ulcerations. The rapidly fatal course thus gave the opportunity of seeing the condition of the colon in the acute stage. Early cardiac failure and anuria were unusual and perhaps due to toxins. Dr. Herringham thought that ulcerative colitis was almost certainly due to a special bacillus. Dr. H. H. Tooth's experience in South Africa led him to believe that these cases were in reality dysentery—the post-mortem appearances were the same. Dr. H. P. Hawkins admitted that it was hardly possible to distinguish these cases from tropical dysentery. He had applied in two cases Shiga's bacillus and obtained agglutination. He thought it best to open the colon early. Dr. Norman Dalton attributed the differences to a varying virulence of the organism. Dr. Weber described a case of dilatation and hypertrophy of the colon (Hirschsprung's disease) in which ulcerative colitis came on and was fatal. Dr. A. M. Elliott said that in dysentery the post-mortem appearances often resembled those of kala-azar. Dr. S. West held that the cases were dysenteric. Mr. Symonds had tried washing out the colon from the appendix in two cases without benefit. The point to consider was at what stage to perform colotomy. Did colitis terminate in recovery? Dysentery certainly did. Dr. Phillips, in reply, said that if ulcerative colitis was identical with dysentery there were many more cases of dysentery in England than there were a few years ago. He had examined for Shiga's bacillus with a negative result. He declared he had witnessed recovery in undoubted cases of ulcerative colitis.

The Hunterian professor of surgery, Mr. D. J. Armour, has given three lectures at the College of Surgeons on the "Surgery of the Spinal Cord and Its Membranes." In opening the course he remarked that when he chose the subject he vainly imagined he could comprise in the three what he proposed to say, but he found that spinal cord tumors alone might have sufficed for the whole course. This he thought a striking proof of recent advances. Other lecturers and authors will sympathize with him in his miscalculation and some, I doubt not, will congratulate him on the skill with which he condensed his teaching on the important subject. He devoted the first lecture to spina bifida, the second to fracture dislocation so far as it related to injury of the cord, and the third to spinal cord tumors on which, as he remarked, the science and art of surgery now occupies no uncertain ground.

The second International Congress on Sleeping Sickness has been sitting all the week. As it is regarded as a continuation of the first conference, Lord Fitzmaurice again presided and welcomed the delegates in the name of the British Government, at whose invitation it assembled at the Foreign Office. Seven countries are represented. The proceedings of the first day were formal and subsequently the conference has discussed very fully the Draft General Act drawn up by the British and German Governments and the Italian chief delegate has set forth at length the views of his Government on the steps that should be taken to combat sleeping sickness.

A Royal Commission on Whiskey is now sitting and the other day some striking evidence was offered by a medical man in defense of this spirit as a therapeutic agent and of "pot-still" as against "patent-still" whiskey. It was Dr. William Murrell who undertook this rôle, and, questioned by Dr. Buchanan, he said whiskey had almost entirely replaced brandy in practice, but in the last year or two the old pot-still article had been mixed with spirit prepared in the patent still and thereby its value diminished. He would not prescribe such a spirit. When whiskey did not produce the effect he expected he ordered the genuine pot-still to be obtained and he had then had the result. He had tried rectified spirit in typhoid and pneumonia without benefit. He then tried pot-still whiskey with marked beneficial effect. The by-products had no deleterious effect if taken in solution in the whiskey, though they might be toxic if separated and taken next. Pot-still whiskey was a stimulant to the heart, blood-vessels and nervous system. The effect was temporary and that is why it was given every four hours and sometimes every alternate hour. The patent spirit did not deserve the name of whiskey, did not contain the by-products which gave it the flavor and odor by which it was made relishable and wholesome. The genuine article improved by age because the by-products increased. He suggested that as pelagra was caused by eating maize, the pot-still spirit, largely made from it, might also have deleterious effects!

In reply to Dr. Bradford, he declared that, though surgeons might still use brandy, physicians, in his opinion, preferred whiskey. He admitted that the pharmacopœia recognized brandy but not whiskey. In either he thought the alcohol of little value, the work being done by the by-product—whiskey was largely used in insomnia, the "night cap" was well known. Pot-still was more rapidly absorbed than patent, judging by the pulse! On this Dr. Bradford remarked, "A very interesting result of your experience, is it not?" and Dr. Murrell replied, "Yes, I am quite clear that I have obtained results with pot-still which I failed to get with patent whiskey. I never looked at either from the point of view of the alcohol being used as a food."

Asked by Dr. Horace Brown whether the difference in the ethers or by-products would not be less than one-eighth of a grain in one wineglassful, Dr. Murrell said: "Well, I can't go into calculations; I can only speak as a physician, not as a mathematician."

At this point the commission adjourned until next Monday. How far they were impressed by this advocacy of pot-still whiskey we must wait for their report to see. Meantime doctors can think it over.

The following researches are authorized by the local Government Board under the Parliamentary grant: 1. Further studies by Drs. Andrewes and Horder as to methods of inhibiting in the animal body the activities of infection by certain cocci. 2. A study of the various forms of pneumonia, especially in children, by Mr. Foulerton. 3. A study of acid-fast bacilli in butter, by Dr. Nabarro. 4. An investigation of the injurious gases evolved during artificial illumination, by Dr. J. Wade.

By direction of the Public Health Committee of the County Council, Dr. Hamer includes in his report a note on the possible conveyance of disease by flies. Referring to the observations of Dr. Niven of Manchester on the simultaneous prevalence of diarrhea and flies last summer, Dr. Hamer points out that contamination of food and loss of sleep sometimes caused by the insects are injurious influences of a serious character.

Dr. L. S. Forbes Winslow has been fined £50 at the Middlesex sessions for what he considered a technical offense under the lunacy acts—aiding and abetting a woman in boarding and lodging a lunatic at a house not licensed under the act.

The chairman said every medical man ought to know the provisions of the act. Dr. Winslow, as an expert, must have known the lunatic's condition. To show it was anything but a mild offense, the penalty must be appreciable though not heavy. The keeper of the house might very well have relied on Dr. Winslow. He was fined £10.

The death of Mr. E. R. Bickersteth, consulting surgeon of the Liverpool Royal Infirmary, recalls a passed generation, his father having been his predecessor at that hospital, and both having been eminent operating surgeons and otherwise distinguished. The recently deceased became M.R.C.S. in 1851, soon after settled in practice in his native town, and in 1857 was appointed surgeon to the infirmary, at the age of twenty-eight. There he worked for more than thirty years, devoted great care also to teaching, and was always in the front of surgical progress. He was one of the first to follow the antiseptic system, Lister having been a fellow student and friend. He has been retired for many years, but his son is now surgeon to the infirmary, the third generation in the position.

Dr. Andrew Halliday Douglas, ex-president of the Royal College of Physicians of Edinburgh, died on Tuesday in his eighty-ninth year. He took his M.D. in 1840, his M.R.C.P. in 1843, both of Edinburgh. He had served for many years as physician to the Royal Infirmary and also to the Chalmer's Hospital. He had been retired for many years, but numerous friends and pupils keep his memory green.

A Pioneer Surgeon.—Dr. Antoine François Saugraine settled in St. Louis in 1800 and was the first surgeon to practise regularly west of the Mississippi river. He is credited with being one of the first to make lucifer matches in this country.

THE AWAKENING OF CHINA IN MEDICINE.

To the Editor of the Medical Record:

Sir:—An ordinary native Chinese doctor, Wong-Yik-Chee, practising entirely among his own countrymen, was reputed to have made extraordinary cures with two or three American patients, and twenty-five native patients were awaiting their turn when I paid him a visit. He was then making his weekly visits to the various towns along the China coast, with two interpreters, who generally accompanied him to dispense his prescriptions, usually small powders and pills. I found him adorned with huge circular horn-rimmed spectacles and thin patriarchal chin whiskers, sitting behind his counter with his stock of remedies which is necessary in practising the healing art.

There is not yet a college for the study of medicine in China, but two are now under way, one at Singapore and the other at Shanghai. Anyone can proclaim himself to be the medicine man of his district. At times he is required to do some surgery, which is very crude and primitive, for the barber is still the recognized man for all ills. It is the custom for a Chinaman to visit his barber every week to have a general overhauling; first the head and face are shaved; second the ears are scraped and cleansed with a small bush made of duck's hair; third the upper and lower lids are scraped with a dull-edged knife, all granulations being smoothed away, and then an application is made, with a duck's hair brush, of salt solution. This is the reason one will find so much blindness in China, as they take no antiseptic measures whatever: all instruments are held in the operator's mouth during the process of operation. Finally the patient's back is massaged, and after paying a fee of three cents and no tip he leaves the shop, feeling clean outside, but now must consult his regular physician.

After going through the usual examination, which is a form of military inspection, Dr. Wong-Yik-Chee will diagnose the case and treat it, unless a devil happens to jump down the patient's throat. If this has happened, the doctor can do the patient no good until he promises to set off one hundred fire crackers to drive the devil away from his body and to make a daily visit to the joss-house. This he does, and after five days he again consults the doctor, with a feeling that he has left the devil behind or with a friend he had no use for. Dr. Wong-Yik-Chee is then not slow to take note of the good prognosis, although he may not remember his patient at all. However, being assured that the devil is no longer in him, he tells his patient he can now help him, and gives him the usual pills given to all those whom the devil has left.

Presumably on account of the high fee, 25 cents, these pills are regarded as an infallible cure for any sickness.

What a Chinese pill may consist of: (1) Spotted rhinoceros horn. It appears that the ordinary variety is of little value, but the spotted horn is a wonderful cure for intestinal troubles, at least so says Dr. Yik. The spotted rhinoceros horns come from Southern China and in the market at Singapore a single specimen will bring as high as $25. Tiger bones, when ground to a powder and mixed with Chinese wine, make a great blood tonic, which is used by all classes of Chinamen in Northern China. The recipe is held by a firm in Shanghai, who have become very wealthy by the sale of this tonic. (2) Old deer horns are boiled down to make the medicinal glue which binds the fifty ingredients composing the average Chinese pills. As in these one may get anything from a pinch of gunpowder to powdered cobra tail dust, it is not the fault of Dr. Wong-Yik-Chee if just the right kind of specific escapes the patient.

Equal in medicinal efficacy to the above are three high-grade tiger remedies, the eyeball, liver, and blood. As may be imagined, tiger eyeball, the genuine article, can be prescribed for only the exceedingly wealthy Chinese. Similarly the liver, when dried and reduced to a powder, is worth its weight in gold all over China. Tiger blood, when evaporated to a solid at a temperature of 110° and taken in the form of a powder, is believed by all Asiatics to make a redoubtable warrior out of the most craven-hearted.

As liniments the Chinese physicians pin their faith to the fats and oil of serpents and the bile. Apparently the more deadly the serpent the greater is the benefit to be derived from its extract, but the chemist must have three various kinds to make one set. These are separated by the chief in charge and he labels them, one for the head, the second for the body, and the third for the legs. When these three drugs are well preserved in ginger and orange peel they bring thirty or forty times the cost of their preparation.

Application of hot pitch poultices are used by the Chinese physicians who attend the poor, as no drugs are required to cure their ills. The effect is usually the same.

After the patient has made the rounds of the barber and traveling physician, he now looks up his dentist, whom he will find on any street corner in all large Chinese cities. One is greatly impressed by the seriousness of this gentleman, who is always reading and thinking of his collection of some two thousand teeth on a table and a few bottles of some secret drugs which upon inquiries my Chinese interpreter informed me contained the moisture of the inner side of an old coffin, which was collected after being buried some ten years. A dentist in China is called a "boxer" by all Chinamen, for he is supposed to have great strength in his arms and hand, and also some great magic power.

After we had waited some twenty minutes, a patient came along and the operator arose with great dignity to receive his patient. After examining the teeth, he inserted his left forefinger around one of the molars and out it came with a few twists of his finger, and then another, in the meantime the patient swallowing the blood from the bleeding cavity. Everyone stopped to see the operation, so that after a few minutes standing room was at a premium. After pulling the first two teeth, the operator now makes a deal with his patient in regard to the rest, as there is no charge for the first two. He will now pull as many as the patient can stand and pay for. Upon inquiries, I found the operator had pulled ten teeth for this patient, who had agreed to settle for eight at the rate of two cents gold for each tooth, and I must say that the operator certainly did earn his fee. I tried to congratulate him upon his good work, but he would not have anything to do with a foreign devil, and I began to think he was afraid of being infected by an American.

At the time of making these notes in Shanghai, January 20, 1908, the Chinese authorities had under consideration a beginning made by a German physician at this port to open this spring a German-Chinese school for the study of medicine in Shanghai, so that the average young Chinaman of brains can get a chance to study in his native land. As the city of Shanghai affords a student many advantages in having a general hospital and several clinics under European management, it is not too much to expect that in five or six years a class of one hundred students will receive medical diplomas from the Shanghai Medical College and will go forth into the world to practise as doctors, equipped with as thorough a knowledge of their profession as could be gained in most of the seats of medical learning in the West. In a few years they expect to open other institutions for the study of law and engineering, or any of the other subjects which Chinese students now go to Japan to be taught. As China is in much greater need of scientists and scholars than of politicians, its well-wishers would seem to have ample reason in desiring to keep her students at home. The future history of the German-Chinese School of Medicine will constitute a fair test as to whether such a policy is feasible or not for the present young man of China who is anxious to rise in his own country. The student problem, which now threatens to become a very dangerous one, would thereby be solved in the most triumphant manner and the most vital interest of the empire would be materially promoted by the practical scheme which this enlightened German physician has proposed to the Peking Government.

China at the present time naturally looks to Japan for instruction in modern science. The Japanese realize that the Chinese Government needs thousands of teachers, so the Japanese instructors are pressing in into all professional works. From what is seen of the modern Chinamen and of their astounding capability as students, their diligence, endurance, attainments, patriotism, and solidarity of feeling concerning the coming greatness of China, one cannot but feel that the future of this country is assured. The advances will be along the lines of the useful arts and sciences, and the West need not fear any military aggression on the part of the Chinese Empire.

James F. Donnelly, M.D.

New York.

Voluntary Ambulance Service in Vienna.—Twenty-five years ago a voluntary street ambulance association was formed in Vienna. That year its services were required 2,000 times; last year nearly 30,000 times.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 19, 1908.

The Use of Fat-Free Milk in Infant Feeding.—C. W. Townsend says that many infants are condemned to a low proteid diet on account of the difficulty they have of digesting, not the proteids, but the fats that go with them. The use of dilutions or modifications of weak creams instead of the strong creams, so commonly advised, and the earlier recourse to undiluted cow's milk would, in the light of these studies, appear to be a more rational procedure. He further reminds us that exact imitation of the percentages in woman's milk is far from being the solution of infant feeding. We must take heed lest we worship the fetish of percentage feeding too blindly, for, no matter how cleverly we calculate the fractions, or how nicely we split the proteids, the resulting mixture is still cow's milk and not woman's milk. The main conclusions of his experience thus far with fat-free milk are expressed in the following propositions: (1) While fat is very necessary to the normal infant, it is more often given in excess than is generally supposed. (2) Excess of fat may cause one or more of a number of symptoms, as, for example, constipation, white and "curdy" stools, a ravenous appetite with atrophy, convulsions. (3) In gastrointestinal disturbances it is desirable to exclude fat. (4) The proteids of undiluted fat-free milk appear to be remarkably well borne even by young infants, and there is an absence of so-called curds from the stools.

The Serum Treatment of Epidemic Cerebrospinal Meningitis.—C. D. Hunt recapitulates the various steps in the elaboration of the serum treatment of this malady up to the present time. His personal experience with the Flexner serum comprises 15 cases. Of these 8 have completely recovered, 2 have died, and 5 are still pending. Of the recoveries, all were free from any of the usual sequelæ of the disease. Both of the fatal cases had been running for a considerable time before coming under observation. Of the 5 pending cases, 4 are convalescent, and will undoubtedly recover. Detailed histories of the cases are given. Naturally, the serum must be early in the disease. The author believes that we can safely conclude that in any event it does no harm. In all but one of his cases the correctness of the diagnosis was proved by the finding of the *Diplococcus intracellularis* in the cerebrospinal fluid. The effects of the serum may be delayed at times, but in the majority of cases the good effects are even startlingly prompt in their appearance. The author admits that his series of cases may have been exceptional, and that much remains to be proved in regard to the Flexner serum, but believes that we are justified in urging a widespread trial of the serum in this disease.

New York Medical Journal, March 21, 1908.

How to Estimate the Functional Power of the Heart.—P. C. Franze calls attention to the value of the following methods of examination: (1) Blood pressure. In absolute insufficiency of the heart muscle, pressure fails. Yet here fall of the blood pressure is no criterion of cardiac weakness. Far less is high pressure a sign of a strong heart. The reasons for this are that the former may be due to undertension, the latter to undertension in the arterial system. So far, therefore, the value of blood pressure is minimized as a means of judging the cardiac power. (2) Pulse.—Frequency, rhythm, and volume of the pulse are quite useless in themselves as criterions of the heart's strength for they are subject to nervous influences. (3) Respiration.—Dyspena in rest speaks for cardiac failure, but the reverse, its absence, is no guarantee for a sound heart. (4) Urine.—Scanty urine, high specific gravity, and albuminuria are signs of a weak heart, if other sources are excluded. But the absence of these signs is no proof of a sound heart. (5) Cyanosis.—This, in a person with sound lungs, is a valuable adjunct to the diagnosis of a weak heart. (6) The size of the heart.—As a rule, a heart of sufficient functional capacity is nondilated, and when incompensation sets in begins to dilate. So, naturally, the size of the cardiac diagram is in some degree an means of forming an opinion as to the organ's functional capacity. But for this purpose, of course, only the most exact measurements can be relied upon. Such ones can only be made by the various *x*-ray methods.

The Question of Sour Milk.—After a reference to the use of sour milk in various countries of the Orient, L. Haim considers its use in therapeutics and its industrial applications. He discusses the various varieties of koumyss and calls attention to the various fraudulent preparations which have been imposed on the public. Such, for instance, are the following: Milk to which a sufficient quantity of any acid has been added to coagulate it, and afterwards, as is practised in soda water drinks, adding carbonic dioxide under pressure of 1 to 2 atmospheres. In another case a similar beverage was obtained by adding to milk some sugar and baker's yeast and keeping until fermentation had occurred. In order to prevent such undesirable practises, the public ought to be very careful in their choice, and preference should always be given to those possessing the guarantees necessary in such cases. No matter whether the product is manufactured by or under the supervision of a physician, the product should be registered with guarantee of a definite chemical standard and standard of bacteriological compositions, according to the regulation of the pure food law.

Symptomatology and Diagnosis of Nephritis.—D. Vander Hoof adopts the classification of Senator, and presents the subject under the following headings: (1) Acute nephritis: (*a*) parenchymatous, (*b*) diffuse. (2) Chronic diffuse nephritis, without induration (chronic parenchymatous nephritis). (3) Chronic indurative nephritis: (*a*) secondary induration (secondary contracted kidney), (*b*) primary indurative (chronic interstitial) nephritis, (*c*) arteriosclerotic induration. Under each heading symptoms and diagnostic considerations are presented in considerable detail.

Treatment of Eczema in Infants and Young Children.—J. M. Winfield enumerates the various plans of treatment which have proven efficient in his hand, following the usual conventional methods. He notes that children fed on sterilized or pasteurized milk are more subject to reflex eczema and disordered digestive organs than are those fed on plain or modified milk, and if the former varieties are given to children already having the disease, the latter becomes aggravated. The dermatoses with which it is most often confounded are scabies, impetigo, erythema, and syphilis, and differential points are enumerated. He notes that it would be better for the cutaneous integrity of the infant if water for bathing could be avoided, and some bland oil, such as olive or almond, be substituted; but it is almost impossible to properly remove crusts, soiled secretions, and débris without water—yes, even soap and water! The water should be soft, rain or spring water, but if this is unattainable, water that has been boiled and cooled will be found quite as good; bran baths, to which a small quantity of sodium bicarbonate has been added, will often be found useful; castile, or the superfatted soaps, can be used when soap is indicated, but it is better to use as little soap as possible, for even the mildest will irritate some skins. After the child has been thoroughly dried, the body, diseased portion and all, should be thoroughly inuncted with some bland grease, such as cold cream or almond oil. The physician should be careful to prescribe a perfectly fresh oil or the best cold cream, for it is a fact of common observation that much of the olive or almond oil procured from the drug store is apt to be rancid, and the cold cream so badly made that it acts injuriously on sensitive skins.

Journal of the American Medical Association, March 21, 1908.

Injuries of the Spinal Cord.—A. R. Allen discusses at length the injuries of the spinal cord, due to external violence, such as gunshot wounds, fracture-dislocation with involvement of the cord and involvement of the cord in spinal concussion without spinal lesion. Stab wounds of the cord are not considered. After describing the anatomic conditions, he points out the liability to injury of the different regions of the cord. A vertebral dislocation without injury to the intervertebral disc is considered by him an absolute impossibility in spite of the numerous instances reported to the contrary. More careful histological study, he thinks, would have revealed an injury. Fractures and dislocations in the thoracic region, above the tenth thoracic vertebra, are not so frequent as those in the cervical region or as those below the tenth thoracic vertebra. In the upper thoracic region, dislocation without fracture is impossible, and, while it is theoretically possible in the lumbar region, the vertebræ slipping forward or backward, there are many who think that fracture always plays a part. In the cervical and lower thoracic region self-reducing dislocation without fracture frequently takes place. It has been claimed by many that the spinal musculature is a preventive factor against dislocation, but Allen considers this an error. A number of cases are on record, however, in which fracture has been caused wholly by muscular action. In injuries to the spinal column the cord may be injured in various ways, transversely squeezed, cut in two, obliquely, or even longitudinally lacerated. Allen reports nine fatal cases, with autopsy; six of them following fracture-dislocation; one due to gunshot wound; one was a pure self-reducing dislocation without fracture, and one followed spinal concussion without spinal lesion. In his comments

on these cases he calls attention to various special features, such as the hematuria that sometimes follows, even with no kidney trauma, which he thinks can be explained by a traumatic anemia causing necrosis of renal parenchyma; the question of erection centers in the cord, as shown by penile turgescence; the danger from operative interference; the cause of hematomyelia in simple spinal concussion, etc. As regards operation, he takes a conservative position, but says that in compound fractures it may be often advisable, but here one should do as little as possible in the way of removal or reposition of fragments. Of course, if there is a lamina driven into the spinal cord, its removal is indicated, but any attempt to remove all existing débris is condemned. It is better to trust to Nature, with the aid of immobilization. When the canal is opened the greatest care should be taken to avoid pressure on the cord, and he would remove blood clots, etc., by irrigation with warm sterile salt solution, after time has been given for the oozing from small vessels to cease, rather than by sponging. There is much testimony in favor of operating in fracture-dislocation involving the cauda equina. The treatment of the bladder troubles and the trophic disorders must be carried out along the lines of general medicine and surgery.

An Endemic of Cancer.—A. L. Tynes gives an account of an endemic of cancer in Fisherville, Va., and vicinity. About thirty years ago there was a very high mortality from this cause, then for about two decades there was comparative immunity from the disease. Within the nine years, 1898 to 1907, there were 18 deaths from cancer out of a total mortality of 105, or 17 per cent. Heredity does not appear to play any important part in the incidence of the disease. There is, however, some suggestion of house infection in the details as given. In a nearby city, within an area a little larger than a city block, twelve cases have developed during the last seven years, and this in a city in which the physicians say there are elsewhere very few cases of cancer. Tynes thinks the facts in these localities point strongly to an infectious organism transmitted directly or by means of a host. A number of interesting details are given, and the article is illustrated.

Sex Life of the Tuberculous.—W. H. Peters considers it demonstrated by observation that there is, in consumptives, an abnormal sexual excitement or erethism that leads them to excess that is liable to be disastrous. He attributes this to the enforced idleness, the temperature and toxins, the forced feeding essential to the cure, the tonics employed, and, in some cases, to a certain recklessness induced by the disease. The tendency may be obvious even to the last moments of life, and it is rather remarkable that the indulgence does not more often have the fatal effects that are sometimes observed. In sanatoria much can be done in the control of this factor, but difficulties are encountered even there. These are still greater in the home treatment that is all that is available for the majority of consumptives. Here the physician can only advise, but he should point out the dangers and insist on the patient sleeping alone and on continence in all respects. The danger to the other partner and to offspring must also be insisted on. He considers absolute abstinence from sexual intercourse one of the most important things to consider and one of the hardest things to insure in the home treatment of the "great white plague."

Traumatic Pneumonia.—J. J. King reports a case of pneumonia, observed about three weeks after the swallowing of a carpet tack, in a child aged six. Later the tack was coughed up and the patient returned to her normal health. He remarks on the grave prognosis in such cases when treated by the expectant plan, but thinks that with Killian's method of examination by introducing long tubes in the bronchi and thus locating and removing the foreign body, only an occasional patient should be lost. Brief notes of cases illustrating the varieties of traumatic pneumonia, from injuries such as contusions, as well as from aspiration of foreign substances, are appended to his account of the case.

The Lancet, March 14, 1908.

Five Cases of Appendicostomy.—The case histories are given by J. L. Stretton, who states that of late he has enlarged the opening sufficiently as to allow of easy manipulation and to make a thorough examination of the abdominal contents. The increased risk he regards as infinitesimal and the advantage gained is that the appendix can be placed in a position most suitable for the future passage of the catheter. He fixes the appendix outside by means of a pin passed through its mesentery and closes the wound round it in layers, being careful not to constrict it too tightly. It is a disadvantage to put any sutures through its walls. At the end of 48 hours it may be amputated, but unless there is pressing need for immediate irrigation, it is better to leave it for two or three weeks. Early removal may cause wound infection, which not only prolongs the process of healing, but makes the catheterization extremely difficult, owing to granulations and the retraction of the appendix orifice. The author found colonic irrigation with silver nitrate solution useful in his personal cases. It is often difficult to persuade the patients to continue the irrigation regularly. The dilatation of the orifice is also difficult. In none of the author's cases was there any discomfort. The orifice did not emit any discharge, and was easily kept clean.

Congenital Hypertrophic Stenosis of the Pylorus and Its Medical Treatment.—The history of one case is given by G. Carpenter, who notes that the records of surgical treatment of this complaint show that the infant does not readily tolerate plastic operations on the abdominal viscera, and believes that in time to come we must look on surgery as the last resort. Much attention attaches to the detection of the pyloric tumor. The treatment must be conducted on the same general lines as have been approved in the uncomplicated spasmodic cases. Carpenter has very little faith in the usual antispasmodic remedies and believes that the question narrows itself down to the proper regulation of the diet and its selection with reference to the requirements of each individual child. Regular meals are no less important than restricted meals, and not only are meals that are too bulky to be carefully avoided but the meal must be administered slowly. The dyspeptic infant becomes an inveterate food-bolter, and a meal that is dumped down into the infant's stomach is bound to disagree. The man who is in a hurry to change the dietary because the infant's stomach does not immediately respond to his treatment will never succeed. Success can only be compelled by shaping a course and intelligently sticking to it. It will be found on inquiry that those who claim that they have tried everything have really tried nothing. Ringing the changes on a variety of foods invites dyspepsia, it does not cure it, and such panic-bred dietaries must be avoided. Abdominal massage in the direction of the pyloric outlet has proved efficacious in at least one case. But in regard to topical treatment gastric lavage has a well-merited reputation. Thorough stomach washing with warm normal saline solution should be used twice a day until the complaint shows decided signs of improvement, when it may be tried once a day. That the remedies are working satisfactorily can be seen by the improved condition of the stools. And there are two other precautions that must be taken—viz., to keep the infant's stomach warm and not to upset his digestion by starchy foods.

Treatment in Delayed Chloroform Poisoning.—A. P. Beddard calls attention to the prevalent use of alkalies on the theory that an acute acid intoxication of the body is at least an important cause of the symptoms and fatal result. He regards a mere acidosis as not a poisoning of the body by acids and that it is only when the supply of basic material begins to fall behind that acidosis passes into acid intoxication. In certain conditions of acidosis such as acute yellow atrophy of the liver phosphorus poisoning, etc., systemic or tissue death supervenes far too rapidly to be due to the passage of acidosis into acid intoxication. Hydrazin poisoning, which produces liver changes similar to those of phosphorus presents no acidosis. The same is true in multiple necroses of the liver following hemolytic sera. Hence the author concludes that alkalies cannot be of much service in the treatment of delayed chloroform poisoning, and he declares than clinical experience confirms this view. In chloroform poisoning the somatic cells are starving for fat. When cells are poisoned by chloroform they can oxidize proteids but imperfectly and fats even less well. Consequently as soon as the cells have used up their meager store of carbohydrate, their hungry condition causes a breaking down of tissue proteid and a transference of fat to them; but since neither of these foodstuffs, and especially the fat, is properly utilized, the cells remain in a condition of severe starvation which may rapidly lead to their death through lack of energy. He and other observers have shown that if the poisoned animal is fed with dextrose the transport of fat is prevented because it is no longer necessary; and further, that recovery is much more likely to take place than when the animal is starved. Feeding with carbohydrates, of course, does not prevent the poison from damaging the cells, and it has been found to be useless when protoplasm has been too severely damaged, as in acute poisoning by phosphorus, but carbohydrates do provide the cells with the source of energy which they can most easily utilize, and may therefore prevent their dying from acute inanition and so give them time in which to recover. The author suggests that under the conditions of delayed chloroform poisoning, it would be advisable to feed the patient with dextrose either by the mouth or by enema or continuous

rectal infusion of a ten to twenty per cent. solution or by infusing into the veins a six per cent. solution. It is impossible, to say whether the ingestion of dextrose before the use of chloroform could have any value. It might be possible by inquiry to find out whether an abnormal susceptibility to chloroform is associated before the operation of such food as will keep up the store of glycogen in the body, and whether conditions which reduce this store increase the susceptibility. From animal experimentation it would seem that every chloroform anesthesia must induce some change in the metabolism, and yet the vast majority of patients do not exhibit the serious symptoms of delayed chloroform poisoning.

Lymphangioplasty.—Under this title W. S. Handley presents a preliminary note on a new method for the relief of the brawny arm of mammary cancer and for similar conditions of lymphatic edema. The author states that the permeative spread of a cancer is accompanied by an almost coextensive destruction of the lymph-vascular system. His aim is to provide an artificial lymphatic system for the affected area and consists in the introduction into the subcutaneous tissues of the swollen area a number of buried silk threads running (*e. g.* in the brawny arm) longitudinally upwards from the wrist to terminate in the loose and healthy areolar tissue in or beyond the axilla and spaced out at convenient intervals around the limb which is thus drained by capillary attraction. The operation is closely analagous to the drainage of a marshy field by lines of buried pipes. The details are given of one case in which this plan was followed, and while the author admits that its ultimate results await the verdict of time, he declares nevertheless that they have exceeded his hopes.

British Medical Journal, March 14, 1908.

Excessive Patellar Reflex of Nervous Origin.—P. C. Smith reports four cases in which in the course of mental alienation of various kinds, excessive patellar reflex occurred but later disappeared without any change in the general deterioration of the chronic malady. In the author's experience it is not uncommon for the insane to show contraction of certain individual muscles when they are lightly tapped, like that displayed, only more universally by some emaciated patients and by those in the lethargic stage of hypnotism. The muscle most frequently affected seems to be the vastus externus sometimes of one side only; others are the deltoid, the pectoralis major, the triceps, the biceps, and the muscles of the hypothenar eminence. The patients who exhibit this phenomenon are mostly general paralytics or chronic alcoholics, in either case having organic changes in the brain; but the author has seen it in a case of acute alcoholic insanity that recovered in less than a month, and in a case of simple melancholia which became chronic. This association with cases that are probably free from organic change, and the similarity of the phenomenon to that occurring in emaciation and the hypnotic state, point to its being due to a functional disorder of the cortex. The theory that it is necessarily due to the cutting off of inhibitive currents that pass down the pyramidal tract is hard to reconcile with its occurrence in deep sleep, in old age, in hypochondriasis, in emaciated persons, and even in the healthy. The results of Jendrassik's method of reinforcement are also hard to reconcile with the arrest of inhibition theory. No doubt it is said that this method acts by distracting the attention, and so cutting off the inhibiting currents; but, in the first place, the method may still prove successful (in cases where the reflex is not obtainable without it), even if the patient deliberately directs his attention to the knee while pulling on his hands; and, secondly, it has been shown that the action of one set of muscles does not diminish, but actually increases the energy of the cerebral cortex in other directions.

The Colony and Bromide Treatment of Epilepsy.—A. J. McCallum reports his experience at one of the English institutions saying that the treatment is based on the assumption that early epilepsy is far more frequently the direct result of peripheral irritation than of Gowers' "abnormal state of chemical nutrition, whereby the molecules are more easily detached and their atoms yield with undue facility to the attraction of the adjacent oxygen," and that the liberal use of bromide prevents this peripheral reflex from disturbing the cerebral harmony and saves the brain from contracting the bad habit of epilepsy on the slightest sensory disturbances. The dose of bromide given is that amount which is necessary to control the fits. This is done in some cases by 40 grains a day; oftener 100 grains is required, and as much as 300 grains has been necessary. The author believes that bromide treatment is necessary and curative in peripheral, traumatic, emotional, and toxic cases. Epilepsy being due to severe prolonged, or repeated sensory stimulation of the brain, he uses that amount of the remedy necessary to stop this sensory stimulation. He has seen only three cases of rash out of forty patients forming one series of cases. For those cases originating from absorption of toxic products from over-eating, from unsuitable food, or from constipation, diet is of importance, but for the bulk of cases diet might be summed up in—three meals a day everything fresh, everything limited, flesh never oftener than once a day and three times a week is ample. In the salt-free or purin-free diet he sees no likelihood of good being done.

Hysterical Somnambulism Showing Abnormal Acuity of Vision in the Somnambulistic State.—The patient of J. W. Russell was a girl of 21 years, typewriter and student, of nervous and reserved disposition whose somnambulistic attacks began three years before she came under observation. These attacks are described in full as she was placed in hospital and closely watched. In one of these attacks a lamp light was turned full on her face, but she took no notice. The pupils were widely dilated and responded but slightly. Physical examination showed little of importance. Superficial and deep reflexes were a little exaggerated. In one attack she wrote a letter on a technical musical subject and its composition was free from any errors. The light in the ward where she was lodged was quite insufficient to allow of any writing or work to be carried out by any normal individual, and the author thinks that an abnormal acuity of vision was present during the somnambulistic state.

Berliner klinische Wochenschrift, March 9, 1908.

Hyperemia in the Treatment of Internal Diseases.—Lewandowski points out that the principles of treatment by hyperemia promulgated by Bier are also applicable to many internal and general disorders of nonsurgical nature. Prominent among these are cardiac affections, pulmonary diseases, skin diseases, diseases of the stomach and intenstine, disorders of the vasomotor and trophic nerves, and disturbances of metabolism such as anemia, obesity, gout, and diabetes. While the differentiation between active or arterial, and passive or venous, hyperemia is well founded and to be adhered to, it is frequently difficult to separate the two forms in practice, and undoubtedly in many cases the results obtained are due to a combination of the two. In the treatment of internal disorders it is chiefly active hyperemia that comes in question, though at times the other type is also of service. Hot air is one of the best means of inducing arterial hyperemia, and the application of hot water in various ways is also an effective and convenient method of securing the desired effect. In some cases, as in gastrointestinal affections, hot beverages are of service, while in others hot local baths or compresses may be employed with advantage and furnish a means of treatment that is easily regulated in point of duration, intensity, etc. The action of hot water applications is like that of the hot air and is characterized by local relief to pain, inhibition of bacterial growth, resolution and absorption of exudates, and nutrition of the tissues. They also afford a means of influencing the general circulation and may form a useful addition to treatment having this end in view.

Münchener medizinische Wochenschrift, February 25 *and March* 3, 1908.

The New Municipal Hospital for Prostitutes in Frankfurt.—Hübner says that three and one-half years ago the German Society for the Prophylaxis of Venereal Diseases was founded in Frankfurt and now a further step in the direction of the restriction of these maladies is marked by the opening of a special wing of the municipal hospital devoted exclusively to the care of prostitutes. In this city there is police control of the prostitutes with compulsory medical examination and treatment, and it is one of the aims of the new institution to make the women feel that these measures are for their own advantage. With this end in view care has been taken in the construction of the building to have the four wards of ten beds each as pleasant and agreeable as possible for the inmates, while all outward evidences of restraint of liberty have been avoided. Adequate laboratory facilities have been provided and it is hoped that fruitful investigations, particularly from the standpoint of treatment, may be made. The study of the patients themselves, not as cases of disease but as individuals, is also expected to yield useful material from the social side, and it is the intention by supplying opportunities for useful occupation, reading, etc., to endeavor to wean the patients from their former modes of life.

Rheumatismus Tuberculosus.—Esau understands under this term a destructive process involving the articular surfaces of the joints and leading to serious damage through ankylosis and contractures, but which is purely inflammatory and aseptic, apparently being caused by an

intensive action of the tubercle toxin in a manner comparable to that of the gonococcus in gonorrheal arthritis. The affection is a polyarthritis which may begin with ankylosis, or a number of joints may simultaneously be the seat of pseudorheumatic pains. The inflammatory reaction is not severe but within a few months ankylosis appears, resulting in complete loss of function and putting an end to the pain. Sometimes fever, sweats, and emaciation are present and dominate the picture. There is no tendency to abscess formation or ulceration and the pains vary in intensity like those of rheumatism. A peculiarity is that corresponding joints are frequently affected simultaneously or after a short interval. The ankylosis is usually fibrous and bony.

The Bactericidal and Hemolytic Properties of the Leucocytes and Edema Fluid.—Schneider describes a series of complicated experiments in which the leucocytes obtained by the injection of aleuronat or bouillon into the pleural cavities of animals were subjected to various procedures in order to test their bactericidal and other properties under different conditions. As the result of these observations it appears that the leucocytes may be kept alive for hours after their removal from the body, and that under these circumstances they behave as independent individuals with the power of secreting substances of various sorts for a considerable period. The bactericidal agents are secreted by leucocytes in a manner comparable to the activity of gland cells, and the author believes that bodies to which he gives the name "leukins" are formed which are different from the alexins. The natural protective agencies comprise the alexins of the serum, phagocytosis, and these products of the leucocytes, which are probably an active factor in the results obtained by the congestion treatment. The bactericidal action of inflammatory fluids depends on extracellular leucocyte products, while the lymph of the vessels contains alexin. The hemolytic action of the extracts from lymph glands is different in nature from that of the blood. The blood plates do not take part in the production of alexin.

Fat Absorption in Infants.—Schelble proposes the following method for obtaining an objective guide to the efficiency of fat absorption in infants, though the plan may also be resorted to in the case of adults. Several drops of blood are obtained in the usual way, in infants by puncture of the great toe, and are placed in a tube of 3 mm. diameter which is immediately put in the centrifuge. By means of a platinum wire the fibrin is loosened from the wall of the tube or is carefully drawn out, and the centrifuging is continued. The serum from a fasting individual is clear, but that taken shortly after a meal containing fat is more or less cloudy, owing to the presence of minute fat droplets. The author recognizes five grades of this appearance: Very fairly cloudy, slightly cloudy, cloudy, very cloudy, very heavily cloudy. It is important not to break up any red cells in performing the test as the presence of a red tinge to the fluid makes accurate estimation of the cloudiness very difficult.

French and Italian Journals.

Experiments in General Therapeutics by Means of Antidiphtheritic Serum.—Mongour has treated a number of nondiphtheritic general conditions by means of injections of antitoxin, with the best of results and no bad effects. The effects are almost immediate and in nondiphtheritic angina recovery is so rapid that convalescence is almost absent. He believes that we have here not a panacea for all diseases, but a medication that is worthy of use by physicians in general diseases. Among the diseases that were successfully treated were typhoid fever, septicemia, pneumonia, cholecystitis, malignant scarlatina, and unknown infections.—*Revue Mensuelle des Maladies de l'Enfance,* October, 1907.

The Origin of the Digestive Gases.—Paul Carnot says that normally the digestive tube is filled with gas which makes the abdomen elastic. This is of triple origin: most of it is ærophagus, swallowed gas; in pathological conditions some is of microbian origin; some comes as an exhalation from the blood. Air is swallowed with the food, with the saliva and aside from deglutition in special gulps; some enters the intestine by aspiration. The quantity is very variable. It consists mostly of atmospheric air. A certain amount is permitted by the stomach to maintain normal tension; still more air increases tension beyond normal and then comes the stage of evacuation by the esophagus, or by the intestine. Gaseous fermentation occurs only when food remains too long in the stomach and microbial fermentation occurs. The gases thus formed are carbonic acid gas, hydrogen, foramire, ethylene, and sulphuretted hydrogen from decomposition of albuminoids. Exhalation of gas from the blood by way of the intestine occurs, but to a small degree only.—*Le Progrès Médical,* November 22, 1907.

Treatment of Tuberculosis Based Upon the Antitoxic Action of the Liver.—E. Gerard and G. Lemoine believe that the liver is the defender of the organism against infections and intoxications. Infectious diseases are less severe in persons in whom the liver is in good condition. Based on this theory they have made experiments on the action of cholesterin and its purified principle paratoxine. This has an action of arrest against the evolution of the tuberculous process. Following their success in the use of this substance in animals they have used it in human tuberculosis at the Hospital of Saint-Sauveur with success in the early and second stage cases. In later cases it was of some benefit also. The patients finally used as material of experiment were outpatients who continued their ordinary avocations and life. They used paratoxine in subcutaneous and intralaryngeal injections, and by mouth. Injected the dose was from one to four cubic centimeters per day. It should be given for several months to get a good effect. General condition was improved, digestion and appetite increased, weight increased, cough rendered loose and lessened in frequency and force, expectoration lessened, temperature and night sweats were relieved. Tuberculous laryngitis was relieved and autopsy showed cicatrization. Tuberculous enteritis was especially benefited even in most urgent cases.—*La Tribune Médicale,* November 23, 1907.

Isolation of the Bacillus Typhosus.—Alberto Altobelli has made extensive experiments as to the possibility of isolating the *Bacillus typhosus* from the colon and other bacilli. He worked on the theory that an agglutination reaction could be established for this differentiation. His results are thus given; the method of agglutination is not applicable to the isolation of the *Bacillus typhosus* by means of a serum of the *Bacillus coli.* It is not possible to prepare a polyvalent anticolibacillary serum which will agglutinate most or all of the bacilli of the coli family. A serum prepared from an immunized rabbit will agglutinate only its own particular variety of colon bacillus. Serum of a rabbit immunized against the *Bacillus typhosus* agglutinates also the *Bacillus coli.* The agglutinating power of an anitcolibacillus serum is inferior to that of a typhus agglutinating serum.—*Giornale Medico del Regio Escrcito,* October, 1907.

Treatment of Loss of Substance in Bones.—Pietro Chorone fu Giovanni sums up the treatment of loss of substance in bony structures thus: Whether traumatic, post-operative, or pathological we should attempt the most rigorous asepsis so as, if possible, to get healing by first intention and thus shorten the treatment and obtain repair without deformity. In cavities and loss of substance of the cranial bones grafts of bone, periosteum, and osteocartilage, and absorbable substances may be used. In long bones with superficial cavities grafts are useful; in deep ones the cavities may be filled with absorbable substances. In loss of continuity of the shaft sterilized bone disks are available. In short bones transplantation of bone is better. When we cannot totally arrest the process of suppuration, especially in the tuberculous variety, second intention healing must be permitted.—*Giornale Internazionale delle Scienze Mediche,* September 15 and October 31, 1907.

Abdominal Drainage with Aspiration.—Delassus discusses the advantages and disadvantages of drainage in abdominal operations. He believes that there are some simple operations in which the abdomen may be closed without drainage. But in the majority of more complicated cases it is advisable to use drainage. He thinks that he has obtained better results since he has adopted the practice of leaving a drainage tube in place to remove the fluid which always exudes from the tissues and may be found collected in the posterior cul-de-sac. He uses aspiration each day with a small syringe passed down into the lower part of the abdominal cavity. Asepsis may be as complete as possible and yet there may be some source of infection in the patient herself, or in the utensils or the dressings used. The only real objections are the pain caused the patient in removing the drain or the gauze, and the tediousness of daily dressings. Uselessness, illogical nature of drainage from below upward, danger of infection, and danger of eventration at the point of the tube the author rejects as baseless objections.—*Journal des Sciences Medicale de Lille,* February 15, 1908.

The London Hospital.—Since this hospital was founded, more than 6,000,000 patients have been treated. Every day an average of fifty patients are operated on, and it is estimated that in the course of a year 1,500,000 pills, a ton of cough lozenges, a hundred miles of sticking plaster, and 3,000 leeches are used.

Book Reviews.

THE PROLONGATION OF LIFE. Optimistic Studies. By ELIE METCHNIKOFF, Sub-Director of the Pasteur Institute, Paris. The English translation edited by P. CHALMERS MITCHELL, M.A., D.Sc. Oxon, Hon. LL.D., F.R.S., Secretary of the Zoological Society of London, Corresponding Member of the Academy of Natural Sciences of Philadelphia. New York and London: G. P. Putnam's Sons, 1908.

THE author of this interesting book is a many sided man, a philosopher as well as a scientist, and a writer who charms by the simplicity of his style and the directness of his argument, holding the attention of his reader from the first page to the last. He makes his points with no show of polemics and meets his opponents with a gentle reasonableness which disarms the most captious critic of his theories. To the readers of his earlier work, "The Nature of Man," of which this is a continuation or a supplement, no commendation of the present essay is needed. They will find in it the same optimistic view of man's present and future, and the same fixed determination to dwell on the bright side of man's physical and mental constitution, without glossing over its imperfections, which characterized the preceding volume.

The author believes that most of us do not reach the length of life to which we are entitled, and if a few of us do so it is only through travail and by paying toll to a senility that comes before its time. Death from old age—natural death—is at present one of the rarest of phenomena but it is not impossible of achievement even now, and eventually it will be the normal end of man. Accidents from without it may never be possible to prevent absolutely, but the accidents of disease will in the course of time be excluded, and then man will live out his natural term happily and peacefully, and when the inevitable end arrives it will be welcomed; life having reached its physiological limit, the instinct of its preservation will be replaced by an instinct of death, and the final act will be accepted with the same peaceful content that one feels in dropping off to sleep after a day of pleasurable activity.

The cause of old age, that is to say, of premature and morbid old age, such as senility usually is, is, according to Metchnikoff, autointoxication, which either weakens the noble cells directly or acts upon them as a sort of opsonin, making them attractive to the phagocytes which destroy them and replace them by fibrous tissue. The elaboration of these autotoxic agents takes place through bacterial action in the intestine, and chiefly in the large intestine. The colon is to the author of this book the *bête noir* of human anatomy, serving no useful purpose, and acting only as an immense culture tube for the noxious bacilli. Since the removal of this part is impracticable as yet, the best we can do in our efforts to attain to a healthy old age is to repress the growth of the intestinal bacteria by restricting the intake of meat and sowing the nutritive tract with the friendly lactic acid bacilli. This is done by taking either a pure culture of these bacilli or milk soured by their action.

This, in brief, is the argument of the treatise so far as relates to the subject noted by the main title, but there is much more, and this is the most interesting part, expressed by the subtitle, "Optimistic Studies," which treats of the ascent of man and of the relation of the individual to the species and to society. The limits of this review will not permit a further analysis of the work, which at best would be unfair to the author and unsatisfactory to the reader. It is a book which must be read to be appreciated, and its perusal will well repay anyone interested in the varied topics of human interest of which it treats.

PREVENTABLE BLINDNESS. An Account of the Disease Known as Ophthalmia of the New-Born, and of Its Effects, With a Plea for Its Suppression. By X. BISHOP M.A., M.B. Cantab, F.R.S.C. Eng., Ophthalmic Surgeon to the Belgrave Hospital for Children; Chief Clinical Assistant, the Royal London Ophthalmic Hospital, Moorfields; Senior Ophthalmic Assistant, the Middlesex Hospital; Oculist (with Care of Blind Children), London County Councils Schools; Demonstrator of Pathology, Middlesex Hospital Medical School; late Examiner, Natural Sciences Tripos, Cambridge University. New York: William Wood & Company, 1907.

IN this small volume of 109 pages the subject of ophthalmia neonatorum is discussed, particularly in regard to its economic relation to the municipality and to the State. The disease in all of its phases and the treatment are sufficiently fully and clearly described. Interesting tables of the number of blind in England, particularly in London, are given, together with the percentage due to ophthalmia of the new-born. Measures of prevention are considered in full. While prophylactic treatment is advised, the author does not think that it is wise to make prophylactic treatment compulsory, as he is of the opinion that such a law would be a dead letter. He pleads for compulsory notification on the part of physicians, midwives and attendants, and thinks that the proper enforcement of this measure will go far to prevent the disastrous results of the affection.

The book is printed in large, clear type, and although its economic considerations are largely adapted to the English public it is well worth being read by American physicians.

SQUINT AND OCULAR PARALYSIS. With a Short Account of the Disturbances of Muscle Balance. By E. LUCAS HUGHES, M.R.C.S. Eng., L.R.C.P. Lond., Fellow of the Royal Institute of Public Health; Clinical Ophthalmic Assistant, Royal Infirmary, Liverpool; late Clinical Ophthalmic Assistant, Westminster Hospital; Assistant in the Service des Maladies des Yeux, Laribosière, Paris, etc. Illustrated by the author. London: H. K. Lewis, 1907.

THIS volume of 208 pages is really a work on the motor anomalies of the eye and their treatment. It is divided into three parts, of which the first treats of "Squint," the second "Ocular Paralysis," and the third, "Disturbances of Muscle Balance."

In Part I. a brief history of squint is given. This is followed by a description of "binocular single vision" of the "fusion faculty" and "the relation of convergence and accommodation." In the author's opinion concomitant strabismus is due to faulty innervation and lack of proper development of the fusion faculty and not to inherent excessive strength of certain extrinsic ocular muscles. The treatment advocated, namely, principally by means of orthoptic exercises, is based on this belief. Javal, Parinaud, Rémy, and Worth are largely quoted, and theirs are the teachings followed. If operation is resorted to, which is advocated in some cases as supplementary to the other treatment, it should not be done before the age of nine years.

Part II. contains a chapter on the "Anatomy and Physiology of the Extrinsic Muscles."

Part III. deals with heterophoria and heterotropia. Heterophoria is regarded as a congenital condition due to excess of muscle-power either (*a*) from excessive development or (*b*) from peculiarity of insertion; a condition in which operation is more frequently required than in ordinary squint. Methods of examination are given in full. An appendix devoted to a description of the use of Rémy's diploscope completes the work. The text discloses evidence of a careful study of the subject. The book is well worth reading by all who are engaged in treating muscular anomalies of the eyes.

TRACHOMA, ITS CHARACTER AND EFFECTS. By Passed Asst. Surg. T. CLARK and Passed Ast. Surg. J. W. SCHERESCHEWSKY. Prepared by direction of the Surgeon-General. Treasury Department, Public Health and Marine-Hospital Service of the United States. Washington: Government Printing Office, 1907.

THIS brochure on trachoma is the result of a study of the disease as observed in the United States Public Health and Marine Hospital Service. A description of the disease, "its effect on the community" and "the effect of restrictive legislation" are given by Passed Assistant Surgeon T. Clark. The same ground is again covered by Dr. Schereschewsky, and to this the prophylactic and immediate treatment are added. Some excellent colored plates of trachoma in its various stages are found in the back part of the pamphlet. The work is creditably written.

LE CRIMINEL, aux points de vue anthropologique, psychologique et social. Par le Dr. EMILE LAURENT. Préface de M. le Professeur LACASSAGNE. Paris: Vigot Frères, 1908.

DR. LAURENT is the author of "Habitués des Prisons de Paris." He was interne at the infirmary of the Prison de la Santé, medical inspector of schools, and connected with the Board of Charities of Paris. In these various capacities he has seen and studied the criminal in embryo, as a vicious and ungovernable child, and "full blown." He has also studied him in his environment in various quarters of Paris and in his travels to the "five parts of the world," he has compared his mentalities, crimes, and mental disorders. His style is florid and very entertaining. Among the chapter titles are: "The Morphology and Physiology of the Criminal," "Psychology of the Criminal," "Degeneracy and Criminality," "Responsibility."

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 24, 1908.

The President, Dr. J. Riddle Goffe, in the Chair.

The Optometry Bill.—Dr. Lambert, acting for Dr. Harris, Chairman of the Committee on Legislation, called attention to the Optometry Bill, the hearing on which was to occur Thursday afternoon (February 27), and the strong efforts that were being made to carry it through. This was a very important matter; the supporters had everything to gain and nothing to lose. This bill should be opposed not only by ophthalmologists but above all by the profession at large. A resolution opposing this bill was offered and was adopted by the Society.

Pensions for the Families of Drs. Lazear and Carroll.—Dr. Loughran, member of the Committee on Legislation, called attention to a bill which was now before Congress, giving pensions to the widows of Drs. Lazear and Carroll. A resolution endorsing this bill was offered and adopted by the society. It was also resolved that the Medical Society of the County of New York send a copy of this resolution to the United States Senators and each Congressman representing the State of New York, and also that they be urged to further the passage of this measure.

Treatment of the Opium Habit in India and China.—Dr. W. D. Silkworth, of Brooklyn (by invitation), told of the so-called Malay cure with burnt opium and the method of employment. A demonstration was made before the society of the making of the pill, and how it was used in the pipe. The remedy was discovered by a Chinese wood cutter and its introduction was furthered by Sir Charles King. Six patients were presented to demonstrate the results of the treatment.

The Nature of Colic and Its Diagnosis.—Dr. George Franklin Shiels read this paper. He said the existing definitions of colic were not only misleading, but to a very material degree incorrect. After going over the medical literature of this and other countries, and after a very careful analysis of a series of answers to the question, "Give a short, concise definition of colic, referring especially to its nature and cause," which question he addressed to well-known teachers of medicine and surgery throughout this country, he had constructed the following: Colic was an acute, violent, paroxysmal, spasmodic, periodic, griping pain due to the contraction of a hollow viscus or structure, whose walls were composed of smooth or unstriated muscle, with irritation of the sensory nerves therein, and was produced by an effort on the part of such viscus or structure to rid itself of an irritant or obstruction. While this composite definition was generally true it lacked the one essential element to make it correct, for without the presence of peritoneum there could be no colic. Therefore a proper definition would be: Colic was a characteristic, acute, spasmodic, peritoneal pain wave most frequently, but not always, associated with an effort of a hollow viscus or structure, whose muscular walls were of the smooth or nonstriated variety, to rid itself of an irritant or obstruction, such viscus or structure being either covered by, or in close relationship to, the peritoneum. Dr. Shiels called attention to a paper by Professor K. G. Lennander, of Upsala, Sweden, which was read before the Section on Surgery and Anatomy of the American Medical Association last June (Medical Record, July 6, 1907). In this paper Lennander said: "From my published works it may be gathered that I have not been able to find any abdominal organ innervated only by the vagus or sympathetic nerves which is provided with the sense of pain. Sensations of pain within the abdominal cavity are, according to my experience, transmitted only by the phrenic nerve, the lower six intercostal nerves, the lumbar, and the sacral nerves." Again: "Should this view of ours prove correct it speaks decidedly in favor of a specific character of the nerves of pain. In other words it goes to prove that only the parietal peritoneum is provided with nerves of pain. It is my opinion that all painful sensations in the abdominal cavity are transmitted only by means of the parietal peritoneum and its subserous layer, both of which are supplied with cerebrospinal nerves around the whole of the abdominal cavity." Again: "Pains do not originate within the abdominal organs which are supplied only by sympathetic fibers and the vagus nerves." The work of Meltzer and Kast, of the Rockefeller Institute, and of others, refutes this theory of Professor Lennander and the results of their experiments might be summed up in the statement that the normal gastrointestinal canal possessed the sensations of pain, that the findings of Professor Lennander were based upon a false premise, that the insensibility of the viscera and visceral peritoneum during operation was not due to any lack of sensory nerves but to some inhibitory process; this inhibitory agent was the cocaine used to render the abdominal walls insensitive. In colic the abdominal sympathetic, as well as the vagi, phrenics, and cerebrospinal nerves were collectively the tracts through which this special pain sense was conveyed; the fact that they were supported and conducted toward their terminal destination by means of the peritoneum no doubt altered the pain wave, and gave it that peculiar type which was understood in speaking of colic. Moreover, the inordinately violent and peculiar symptoms brought about by trivial causes were reasonably explained by the multitudinous ramifications and important vital ganglionic anastomoses of these nerves. Other organs or structures not noted in this composite definition of colic, when obstructed, gave rise to pain, but in no sense was this pain colic. No one had ever heard of colic of the vas deferens or of the Eustachian tube, or of the bronchi. Irritation of the vessels and lymphatics in close relationship to the peritoneum doubtless gave rise to pain of a colicky character, which was either directly or reflexly elicited. Having proven to his satisfaction the fallacy of the smooth-muscle-pain theory of colic, he reiterated that without the presence of peritoneum colic could not be developed. He firmly believed that many postoperative colics were due to irritation brought about by other causes, such as blood clots, slight traumatisms, too much handling, exposure to cold, etc. Dr. Shiels believed that if his definition of colic was a correct one, and the extent of the peritoneum and of the wide anastomoses of the abdominal nervous system were kept in mind, all the reflex and typical colics would be more easily understood and accounted for.

Dr. George E. Brewer repeated the definition of colic as given by Dr. Shiels, and said that the intestines, the biliary apparatus, the kidneys, the ureter, the appendix, etc., were all hollow organs and typical colic was produced by explosive efforts. In intestinal obstruction particularly one could see these waves produced by contracting intestine, visible through the abdominal wall. So soon as the obstruction was relieved, the pain was relieved. This was true of the appendix. The presence of a concretion, without fever, inflammation, or evidences of irritation, produced at times the most violent colic. The same was true of stone in the ureter, the kidney, or the biliary passages. A thought that occurred to him was, "Why not say that colic was due to the presence of areolar tissue because this tissue surrounded all organs?"

Dr. Florian Krug asked if Dr. Shiels included in his definition the colicky pains resulting from ectopic gestation and tubal abortion. The most violent colics were those connected with the attempt of the Fallopian tube to expel foreign bodies.

Dr. Ludwig W. Kast spoke of the work of Dr. Metzler and himself on the subject of abdominal pain and sensi-

bility of the abdominal organs, and said he wished to correct the statement quoted with regard to the fact that their experiments concerned solely the sensibility of the abdominal organs of the dog. In that animal the stomach, the small, and the large intestines were sensitive to touch, to heat, to the galvanic as well as the faradic current. But this sensibility disappeared after the injection of cocaine, and this injection might be applied near the peritoneum or far away from it. Lennander, in order to explain the different forms of abdominal pain, made the explanation that the pain resulting from gastric ulcer was not due to muscular contraction, but was due to the absorption of the hydrochloric acid into the tissues of the stomach, and this being carried further down to the peritoneum caused pain.

Dr. Shiels said that Dr. Brewer had misunderstood him; he did not wish to convey the impression that the irritation of the peritoneum caused the pain, but that the type of the pain was given by the peritoneum; it was only when the peritoneum was present that the peculiar type of pain known as colic could exist. The theory of areolar tissue fell to the ground, for this tissue existed in the esophagus, the rectum, and other structures where no colic occurred. The peritoneum was in close relationship with the Fallopian tubes.

The Treatment of Intraperitoneal Hemorrhage from Rupture or Abortion of Tubal Pregnancy.—Dr. Hiram N. Vineberg read this paper. (See page 554.)

Delayed Treatment of Tubal Pregnancy.—Dr. Hunter Robb, of Cleveland, Ohio, read this paper (by invitation). He said he would endeavor to present his own convictions with regard to the treatment of ectopic pregnancy, especially in cases where rupture had taken place, and referred to some of the points already noted in his paper read before the American Gynecological Society last May. Tubal abortion was said to occur in from 75 to 78 per cent. of the ectopic pregnancies, but in his experience the percentage was higher. Most authorities agreed as to the treatment in the absence of contraindications; immediate operation was indicated in the early cases in which there was a positive or a probable diagnosis of ectopic gestation before rupture or severe hemorrhage had occurred. Complete cases of tubal abortion were dangerous because the hemorrhage might suddenly become profuse, and the patient then was said to be in no condition to stand stimulation. Dr. Robb did not believe in this. Frequently one would find the fetal sac plugging up the tube. Patients were often in a state of collapse and operation was advised under the belief that the patient was bleeding to death. As a result of this doctrine he said a great many lives had been lost by a resort to operation, either abdominal or vaginal section. When a surgeon advised immediate operation in such cases, the procedure was open to criticism. Many would recover without operation. Many surgeons were losing cases because they believed that such cases must be operated upon immediately. In dealing with ectopic gestation the first factor to consider was the hemorrhage. It was well known that the quantity of blood was 7.7 per cent. of the body weight in the human; the question then arose, what percentage of this could be lost without detriment. A healthy person might recover after losing three per cent. of the body weight. Therefore, a woman weighing 130 pounds might recover after losing four pounds of blood, or 1,650 c.c. He believed that sometimes these patients recovered not because of the operation, but in spite of the operation. He asked how often the abdomen had been opened in cases of ruptured ectopic gestation and bleeding had been found to be still going on? If hemorrhage was not going on, with the patient in shock, what could be gained by operation? How frequently did one actually see bleeding vessels in these cases? How could we know that the manipulation was not responsible for any hemorrhage encountered? In his experience with over fifty cases he had found threatened bleeding but no actually bleeding vessel. It might justifiably be assumed that there was something faulty in reports of series of deaths resulting from a ruptured ectopic pregnancy. Many operators had reported no deaths from deferred treatment. In many cases immediate operation took away the patient's chance for recovery. Dr. Robb then described his procedure, which gave him satisfactory results. He carefully stimulated the patient with a saline infusion under the breast. If there was no vomiting stimulants were given by the mouth; also morphine was administered either by the mouth or hypodermically. Heat was applied to the body, and the head of the bed was elevated. Strychnine was given. While this treatment was carried on, the operating room was made ready, and so soon as the woman recovered from the shock, operation was performed. Dr. Robb protested strongly against the removal of such patients to the hospital, for this aggravated the condition of shock as it increased the loss of blood. He instanced the condition of five patients who were admitted to the hospital in such a serious condition of severe shock that death seemed imminent. None of the operations were done earlier than from eighteen to twenty-four hours after rupture in these five patients, while in the remainder the periods varied from three to twelve days, with an average of five days. Among his cases there was but one death. In concluding his paper Dr. Robb emphasized certain points: Conservative operations upon the tubes and ovaries now were common, although a few years ago radical operations were deemed necessary. More conservatism in the treatment of ectopic pregnancies was called for. When the diagnosis of an ectopic pregnancy was certain, an operative course was indicated. Many women not only survived the effects of ectopic pregnancies, but recovered without operation. When seen in a state of collapse, operation was not necessarily indicated; when they died, they succumbed from shock and not from loss of blood. Most of the cases when operated upon showed no bleeding from the blood-vessels, unless it was caused by the manipulation. Large quantities of recently accumulated fluid in the abdomen should not be removed suddenly; the vessels should have an opportunity to adapt themselves first to the changed mechanical conditions. Cases in which the bleeding was sufficient to cause death were rarely seen in time to save the patients. The results obtained by good operators who deferred operation were worthy of consideration.

Dr. Brooks H. Wells called attention to the classic monograph of Parr, which was written in 1876; among the 500 cases of ectopic pregnancy which formed the basis for his work, there were 329 deaths, and of these 174 were the result of hemorrhage from an early rupture of the gravid tube. It was not convincing to say that as a bleeding artery in a tube or broad ligament of a dog would not cause death a bleeding artery in a tube or broad ligament of a pregnant woman would not be fatal. Twenty-three years ago it happened that, as the assistant of a prominent gynecologist, he was fated to sit by the bedside of a young woman, inactive so far as efficient aid was concerned, and he saw her fade into death while her surgeons, men prominent and skilled, waited for the reaction that never came. The diagnosis had been made of an internal hemorrhage and the question of a ruptured ectopic pregnancy was considered, but those in charge refused to operate because of the presence of a marked degree of shock. The abdomen was opened after death and a ruptured tubal pregnancy found. Within less than a month the bitter experience was repeated and so great was the impression made by these two cases that never since had he dared to refuse operation to a woman with a bleeding tube, and in a large experience he had never had one die after the bleeding point had been secured. Experience gleaned from multitudes of cases made it certain that many women with ectopic pregnancy would not die if left with-

out any treatment. It was also true that many cases of appendicitis in which operation was urged would recover without operation. But which ones? In the majority of instances the bleeding would be found to have ceased at the time of operation, but there were important exceptions. Where the surgeon had reason to believe that active bleeding was going on, he should not employ stimulants until he was ready to control the bleeding. Dr. Wells' experience was to take out a pregnant tube as soon as he was reasonably sure of his diagnosis, and he had never had cause to regret it. When he considered the pathology of the condition, the probable sequelæ of an early or late rupture, the probable mortality, and contrasted all this with the very slight mortality or morbidity following expert operation he repeated without hesitation that: "Undoubtedly without the necessary surgical skill the waiting policy may be best; but, if the patient with an ectopic pregnancy can be put in the hands of one reasonably expert in abdominal surgery, operate at once. Should rupture have occurred with serious and progressive hemorrhage so that the patient seems in danger of death, operate at once and do not wait to see whether she is to die or recover."

Dr. Howard C. Taylor said there was no question that in the great majority of cases of ectopic pregnancy the bleeding ceased spontaneously. In many of these cases the symptoms came on slowly, they might not be severe and often resembled those of inflammatory conditions, and the correct diagnosis was made only at the operation. Neither in his opinion was there any question that there were a certain number of cases in which the bleeding did not cease spontaneously and the cases died from hemorrhage. If a patient came under observation shortly after an acute onset of bleeding from an ectopic pregnancy, should they wait and trust that the case might be one in which the bleeding would cease spontaneously and ignore the fact that there might be a fatal outcome?

Personally, he would not do so. The operation was not one associated with special shock, and in his judgment the danger of the additional shock of the operation was less than the danger of additional bleeding. He had been greatly interested in Dr. Robb's paper, but there were some points with which he did not agree. That he would operate on a pregnant dog, as he had described, and the dog live, did not prove that bleeding from a single vessel might not cause a fatal hemorrhage as had happened as the result of the slipping of a ligature. While it was true that there might have been some fluid in the abdominal cavity previous to the hemorrhage that might make the amount of blood present seem more than the patient had really lost, it was also possible that some of the fluid parts of the blood would probably be absorbed so that the amount of blood present would not be as much as the patient had really lost. Again, while it might have been proved experimentally that an animal might lose a certain percentage of its body weight and live, it did not prove that a woman might bleed the same percentage of her body weight into her peritoneal cavity and still live. It had been often noted that the blood in the peritoneal cavity was there under pressure and spurted out as the abdomen was opened, and that at the same time there was an improvement in the condition of the pulse, showing that the pressure of the blood in the abdominal cavity might be a factor in producing the shock from which the patient was suffering. His judgment was that the immediate operation gave often the only chance to save the patient.

Dr. Hermann J. Boldt said that the question of the wisdom of operating on patients who were in absolute collapse following a ruptured ectopic pregnancy was one of the greatest importance. All must agree that it was a serious procedure to operate upon a patient in absolute collapse. However, such a patient seldom died from the primary hemorrhage from a primary rupture. He believed it was erroneous to wait and wait until the patient got better and better after a certain period of time. If going to do that, he asked why operate at all, unless certain symptoms set in. How was a surgeon going to tell that a patient would recover by the expectant plan of treatment? As a rule he took the ground that all patients with an ectopic gestation should be submitted to operation unless there were contraindications, when the expectant plan of treatment would be the proper course to pursue. But all other patients should be submitted to operation, and the sooner the better.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held February 18, 1908.

Dr. Onslow Allen Gordon in the Chair.

Blood Transfusion as a Therapeutic Measure.—Dr. William F. Campbell of Brooklyn read this paper.

Bad Air and Good Air, and the Uses of the Latter.—Dr. W. P. Northrup of New York read this paper. He said that old conceptions as to what was meant by bad air, and which were taught in the schools, were that bad air contained a deficiency of oxygen and an excess of carbon dioxide. These conceptions were later supplemented by the observations of Brown Sequard and D'Arsonval, who distinctly stated that there was a breath poison, which accounted for the symptoms produced by confinement in a close room. Paul, one of the workers in Pflüger's laboratory, set out to put this view to an experimental test. He constructed a cubical cabinet whose sides were two meters long, just large enough to enable him to sit within it, in order to study the effects of the close confinement upon his body. He found that when the cabinet was cool he could remain in it for four and a quarter hours without any ill effects. On the other hand, when the cabinet was heated to 72°, at the end of a quarter of an hour's stay in the cabinet these ill effects would appear. There were a band-like sensation about the head, headache, vertigo, nausea, vomiting, and, finally, fainting. If a person outside the cabinet now breathed through a tube the air contained in the cabinet, he did not suffer these symptoms. The introduction of a fan into the cabinet, and, by means of it, the vigorous stirring up of the air, made a decided difference, by retarding or delaying the symptoms produced by close confinement in the cabinet. The question then arose, why did the individual confined in the cabinet suffer from the symptoms, while one on the oustide, breathing the same air, was immune from them? The answer was that the heat and moisture in the cabinet, in other words, the steam jacket surrounding the occupant's body, made the difference. The case of the lady who fainted in the theatre was not one of breath poisoning, but was similarly a practical application of the experiment performed above, that is, it was a case of the presence of a steam jacket about the body, which would not permit the latter to unwarm itself. This unwarming of the body was quite essential for the proper performance of its functions. The ill effects following the stagnation of warm, moist air about the skin were just as important as those following the breathing of foul air. In this sense, one might, with a stretch of the imagination, say that the skin breathes quite as much as the lungs. The diminution of oxygen and the increase of carbon-dioxide in the air were, therefore, not the main causes of the unpleasant and dangerous symptoms, in the acute cases of close confinement, although they had a more far-reaching and important rôle in chronic cases. Pflüger, applying these facts, stated that one should not wear furs, paper, or rubber about the body, since these favored the retention of a steam jacket. It was essential for the proper maintenance of health that the body should be permitted to lose its heat. There was nothing so important as varying the temperature of one's atmospheric environment. In spite of this, people habitually lived in overheated rooms. The steam-heated apartment was an abomination in this

respect. The old-fashioned hospital ward was overheated. At the Presbyterian Hospital the wards were kept during the day at from 60° to 65°, while at night the temperature of 50° to 55° was found sufficient. There was nothing that added so much to the discomfort of the patients as the warm, stagnating air of the hospital wards. They now had an open-air ward on the roof of the Presbyterian Hospital. Recently, through the munificence of Mrs. W. C. Vanderbilt, Sr., they had been enabled to construct a shed over this ward, providing shelter against the sun and wind. There was also a sun room. The beds were on wheels, so that the patients could be moved from one part to another of the open-air ward. It was desirable that the casters should be of wood. The speaker's experience in the treatment of sick children upon the roof was unique. He said that a visit to the open-air ward at present, even with the roof banked with snow, would show cases of double pneumonia, empyema, and abscess of the lung. Under this treatment the patients usually progressed favorably. In sharp contrast to the behavior of similar cases formerly kept in the wards, they slept and ate decidedly better. The speaker facetiously criticized the modern treatment of tuberculosis by means of the window-shack method; in this it was designed to have the patient breathe the outer air, while his body was confined indoors. He thought it was more important that the body should be outdoors as well. In the open-air roof ward, by the avoidance of drafts, there was no danger of catching cold. In fact, it was found that nurses who had caught cold downstairs progressed favorably when assigned to day or night duty on the roof. The avoidance of drafts was effected by means of the shed, as well as by the mode of dressing the bed. This was of great importance. Below the mattress was a layer of paper; beneath this was a blanket, which thus surrounded the mattress completely, and came up on the sides, and was pinned in the middle above the patient. Another blanket was placed on top. In this manner no drafts could reach the patient. The speaker had observed that a tiled flooring on the roof was a disadvantage. The children who were allowed to be up chose to play on the board-covered part of the roof. The open-air ward of the German Hospital had this very disadvantage, and, worse, the entire roof was tiled. The hard, warm, or cold floor did not invite the little feet of the children. In the open-air ward the sick children required less constant care than in the other hospital wards. It was unusual to find the children awake at night, while indoors it was not uncommon to find the little ones at night, their eyes wide open, and also crying continually for water. The idea of the roof ward had already taken hold in the medical community. Roosevelt Hospital was building one that would surpass by far that of the Presbyterian Hospital. Open-air wards were likewise in process of construction at King's Hospital, London, at Shrewsbury, at St. Luke's Hospital, and the New York Eye and Ear Hospital.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held January 21, 1908.

DR. HERBERT S. CARTER IN THE CHAIR.

The Metabolism of Nitrogen and Sulphur in Pneumonia.—Dr. ALEXANDER LAMBERT and Dr. CHARLES G. L. WOLF presented this communication, which was read by Dr. Wolf. So far as they were aware, there were on record no complete analyses of the urine in this affection, which had been made with trustworthy methods, which would especially serve to correlate the metabolism of nitrogen with that of sulphur, and it was on this account that they presented two sets of analyses of the urine out of a series of fifteen which they had made. Among the questions they attempted to answer in this work were the following: Did the breaking down of large quantities of body protein lead to the same relative distribution of nitrogen and sulphur as when the same quantity of food protein was catabolized? Were the end-products qualitatively the same? To what extent did the protection of protein by fat and carbohydrates effect the excretion and distribution of the nitrogen? To summarize, what they found to be some of the unusual features of the metabolism in pneumonia were the following: (1) The very high loss of protein, in spite of the fact that the organism was receiving amounts of food which in the normal individual were sufficient to protect from any loss. It had been shown, moreover, that the addition of protein to the diet did not protect from loss of body protein. All the protein given was excreted in addition to the individual loss which occurred under general conditions. From this point of view, the attempt to spare the body by the administration of protein was merely adding a burden in excretion to the already overtaxed organism. That the addition of fat, or especially of carbohydrate, might protect in a marked degree had been shown by Coleman and Shaffer. It was along this line that feeding experiments with patients suffering from toxic fevers must be carried out. (2) The high elimination of creatinin during the precritical period denoting an increased metabolism of a special and important type. This type of metabolism became subnormal during the postcritical period, when the patient was attempting to recover from the severe drains to which he had been subjected. (3) The excretion of creatin during the toxic period, and the disappearance of this substance from the urine after the crisis. They were inclined to attribute very especial significance to this substance and did not altogether associate it with loss of body protein. The amounts in which it was present were much larger than what was found in urines of starvation, and besides one found the compound in urines which were not at all associated with loss of body protein. (4) The very high amount of undetermined nitrogen, pointing to a disturbance of a type in which the nitrogen catabolism did not go as far as ammonia formation, the end product which was subsequently synthetized to urea. This undetermined nitrogen must be made up largely of substances containing sulphur, for the neutral or undetermined sulphur to a certain extent predominated. What the substances were which entered into this mysterious group was absolutely unknown. They were probably very complex compounds of the sort isolated by Bondzynski and his coworkers, and which had received the name oxyproteic acids.

Dr. P. A. SHAFFER thought that perhaps it would not be out of place to call attention to the rather unusual amount of work which this paper of Dr. Lambert and Dr. Wolf represented. No one, who had not carried out similar experiments, could have any adequate idea of the very large amount of work and time which such a study demanded. In this age of experimentation, too many were in the habit of choosing problems for their research which might be solved in a very short time and by a few experiments. And while, of course, there was not necessarily any relation between the amount of time and the worth of one's conclusions, it very often happened that the value of the results was quite commensurate with the completeness of the observations. Certainly the results obtained by Drs. Lambert and Wolf were of value because of the completeness of the analytical results. Such work would in the end repay for the large amount of analytical drudgery which it demanded, for it was only by such complete observations that one could learn the details of this interesting subject, metabolism in fever. During the last few years knowledge of the normal variations in the excretion of the products of protein metabolism had been materially advanced. Two of the most interesting of these products appeared to be creatinin and creatin. These two substances were very

closely related chemically, but so far as their appearance in urine was concerned, they probably had nothing to do with one another. Creatin was not excreted normally unless the subject had ingested creatin. Creatin did appear, however, in high fever. Subjects of exophthalmic goitre in the acute emaciating stage excreted relatively large amounts of creatin. He said he had found it also in the urine of a woman a few days postpartum. It also was said to occur in fasting. The muscle tissue in the average individual contained altogether about 90 grams of creatin, none of which appeared in the urine in health. These facts indicated that creatin was excreted only when there was a breaking down of muscle tissue, in starvation to greet the physiological demands for energy-producing material; in women just after parturition, because of the rapid physiological resolution of the uterus; in cachexia, and in fever, because of the pathological consumption of muscle tissue, due perhaps to some form of bacterial or other toxins. If this view was correct, we had in creatin a means of knowing whether the muscle tissues were being pathologically drawn upon or destroyed. In pneumonia Dr. Lambert and Dr. Wolf found large amounts of creatinin excreted during the fever, and the amount dropped suddenly with the fall of temperature at the crisis. This was in accord with other recent observations. Creatinin, unlike creatin, was present in large quantities in normal urines and in complete health. The amount excreted was constant for a given individual from day to day, and, as some unpublished experiments of his own indicated, just as constant for every hour during the day. In high fever the amount excreted was increased, but when the temperature fell and the patient was left in a muscularly weak condition, the amount excreted was very markedly below the normal. He believed that, exclusive of fever, the amount of creatinin excreted had a direct relation to the potential muscular efficiency of the individual. Strong and active individuals excreted much creatinin, while subjects who were muscularly weak excreted correspondingly small quantities. After a pneumonia, for instance, he believed that the amount of creatinin excreted was an expression of the degree in which the efficiency of the muscles of the individual had suffered during the disease. Unfortunately, however, one did not have the opportunity of determining the normal excretion of the subject before the pneumonia was contracted.

Dr. Warren Coleman said that he had been interested in the practical rather than the purely scientific side of the work, and it was a matter of great satisfaction to him to find that by means of the diet Dr. Shaffer had spoken of, reaching 4,000 calories, one could protect the body proteid of typhoid patients. He had arranged a special dietary for typhoid fever patients, consisting principally of milk, milk sugar, fat, and eggs; this was a good diet, but not satisfactory from the gustatory standpoint.

Dr. Charles G. L. Wolf said that it appeared that the question of diet was important not only in pneumonia, but in other hyperpyrexial conditions and should be worked out scientifically and practically with material benefit to the patients. It had been shown years ago that in the stage of pyrexia, no matter how much protein one got, the organism got rid of it in the way or urea and ammonia by the kidneys.

Experimental Notes on Artificial Nutrition, with Special Reference to the Hypodermic Method.—Dr. Herbert S. Carter read this paper. He called attention to the inadequacy of rectal feeding in many cases and asked how the nutritive equilibrium could be kept up more satisfactorily than by this means. After reviewing the important contributions to the subject, and the literature on this subject was very scant, he referred to experiments made on dogs with injections of certain agents of nutritive value, and said that he did not think it was unreasonable to believe that the application of the same method might be used with benefit on man.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 28, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	539	200
Diphtheria	405	58
Measles	1813	38
Scarlet Fever	1113	40
Smallpox	—	—
Varicella	135	—
Typhoid Fever	22	4
Whooping Cough	15	3
Cerebrospinal Meningitis	17	8
Malarial Fever	—	—
Totals	4059	351

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending March 27, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Alabama, Mobile	Mar. 1–8	5	..
California, Los Angeles	Feb. 29–Mar. 7	10	..
San Francisco	Feb. 29–Mar. 7	12	..

DIABETES AND THE FOOD FACTOR.*

BY HENRY S. STARK, A.M., M.D.,

NEW YORK.

THE exposition of recent studies of the minute physiology of the functions of metabolism has paved the way for many innovations in the care of diabetics. Advances along this line of research have made it clear that the physician who treats diabetics simply with codeine and a starch-free diet is setting back the hands of the clock. Such a routine is classic and savors more of the antelaboratory period than of the present day of scientific research.

Among the many factors that have contributed to change the principle of treatment, the following are the more important: Our advanced knowledge of the physiological values of the food elements, of their ultimate disposal in the human economy, and of the destination of their end products; a clearer conception of the reaction of the human organism to diet; a better understanding of the genesis of urea and uric acid; the discovery of the detoxicating function of the liver and of the emunctory virtues of the kidneys; a more comprehensive knowledge of the nature of enzymes, and finally the almost patent fact that diabetes is viewed as a biochemical process whose origin is hidden somewhere within the confines of the alimentary canal.

In order to manage diabetics intelligently something more than a passing knowledge of urinalysis is required. The time has long gone when the physician's obligation to his patient was discharged by the mere performance of Fehling's test. The fact that both diabetic and non-diabetic urine may contain other substances than glucose that may cause chemical reduction, and others that may prevent reduction, must not be lost sight of. The objective evidence obtained by a detailed chemical examination of a twenty-four hours' specimen is necessary to indicate the line of treatment in individual cases. The presence of the acetone bodies, the fluctuations in the glucose element, the variations in the normal ingredients, especially the nitrogen compounds, the probable presence of pentose or lactose, are all factors which must be determined. In borderline cases the reduction tests must be supplemented by others, such as the fermentation, and the phenylhydrazin test. In all cases it will be found useful to adopt the following routine for the identification of glucose. Suspend all drugs for one day, then secure a specimen of a twenty-four hours' collection, test the same for albumin which should be removed by boiling. Next filter the urine at least once through animal charcoal, which frees it of urea, uric acid, creatinin, coloring agents, and other ingredients. Thus we obtain a product which it is possible to examine for glucose with some degree of reliability. In cases where doubt is felt as to the nature of the reduced substance, the two control tests before mentioned should be employed, as well as the orcin test for the pentoses. These formalities are not mere pedantry but really essential. For you will be surprised how many disturbing factors may prevent or cause reduction. These are not only chemicals, but certain food ingredients and some products of intestinal digestion. In those diabetics who have a slight glucose output, the reduction may be completely masked by the presence in the urine of the by-products of a disturbed metabolism.

A significant condition for the successful management of diabetics is a comprehensive knowledge of scientific dietetics. For as far as the treatment by drugs is concerned, diabetes belongs to the category of therapeutic failures. There are few subjects connected with the practice of medicine so little understood by the profession as the food factor in health and in disease. And yet when we consider that the number of diseases attributed to a disordered nutrition is constantly increasing, it is to be commented upon that our medical institutions should devote so little attention to the science of dietetics, and that the vast majority of them should furnish no facilities for acquiring practical instruction in this branch of therapeutics. Probably in this era, when the science of bacteriology dominates the spirit of research, the problem of feeding has not yet caught the fancy of the medical mind. But I believe a healthy sentiment is being aroused in favor of the study of foods and feeding. The efforts and labors of the United States Department of Agriculture deserve especial mention. In the field of pediatrics the subject has been threshed out to a nicety; in other branches it has met with scant favor.

The percentage composition of various foods, the nutritive values of their components, their potentialities as conservers of heat and creators of energy, their economic values with reference to their assimilative qualities, are unerring guides to the proper management of diabetics. To prescribe the right food at the right time is an art in itself. And to prescribe a diet which shall not transgress the limits of sugar-assimilation requires more than a passing knowledge of food constituents, and the methods of their preparation. As stated by me in a previous communication, the question of diet in diabetes is not so much one of restriction as it is one of regulation. It is not a question of how much is swallowed, as it is one of how much is absorbed. It is manifest, then, that from a dietetic standpoint there are two practices in vogue which should be condemned. Firstly, the danger connected with a one-sided diet, and secondly, the danger of latent starvation due to subalimentation. The former results from an inordinate indulgence in nitrogenous food, the latter from a too rigid exclusion of carbohydrates.

A proteid, or any other one-sided diet, cannot be indulged in for a long period with immunity. Path-

*Read at a meeting of the Eastern Medical Society, March 13, 1908.

ological effects will eventually manifest themselves. Physiologically, the economy shows no predilection for any one of the proximate food elements; each has its own service to perform, while all three are essential for the maintenance of a physiological equilibrium.

A continuous diet rich in nucleins will result in nitrogenous excess with its evil consequences, such as a subalkalinity of the blood, emaciation, a tendency to coma, irritation of the kidneys, cutaneous lesions, disturbed liver function, intestinal manifestations due to the large amounts of ingested extractives, arthritic affections, and autoinfections from toxins formed in the body. Further, the custom of overcharging the body with a nitrogenous diet may tend to the formation of lower oxidation products, such as the xanthin bases, which also may cause constitutional disturbances. In short, excess of proteids means excess of waste products.

If these changes are liable in healthy subjects, how much more liable are they to occur in diabetics whose physiological functions are below par for years?

The average healthy subject produces about 30 grams of urea in twenty-four hours, on a mixed diet. In diabetics, an increased elimination is the rule, due firstly, to the one-sided diet and secondly, to an increase of tissue-destruction. When a patient is on a rigid proteid diet, say 400 grams per day, which by the way, should be the maximum allowance, frequent tests for acetone and diacetic acid should be the rule. Positive reactions would point to a reduction of animal foods, and the exhibition of carbohydrates. So you see that the orthodox belief that diabetics should religiously eschew carbohydrates is not sanctioned by scientific analysis. Modern chemism has entirely upset that tradition. In point of fact there comes a time in the life of most diabetics when foods containing starches are absolutely essential. When the urinary index points to an acidosis or when progressive emaciation or an obstinate neuritis is a marked feature, such carbohydrate food as cereals, bread and potatoes, should be pushed to the limit of assimilation, in order to check the formation of the acetone bodies. It is an acknowledged fact that this latter group may put in an appearance even in healthy subjects when fed for a time on a nitrogenous diet. In grave cases of diabetes with alarming disturbances of the general nutrition, it is surprising how quickly some patients respond to the administration of cereals and vegetables with low sugar contents, even though the glycosuria persists. In the diabetes of the aged, this dictum is especially true. Too much stress should not be placed on the severity of the glycosuria, for this phenomenon is often a delusive guide to the patient's condition; more reliable as an index of the severity of the disease is the loss of nitrogen and the rapidity with which the body fat is burned up. An excessive acetonuria usually can be arrested by exhibiting measured quantities of carbohydrates beginning with 50 grams and going up to 100 grams daily. This behavior of the metabolic functions has not yet been explained. It is presumed that the end products of fat digestion and those of starch digestion are antagonistic in their final catabolism, or else the carbohydrates protect and prevent proteid loss.

Fat as an article of diet has a greater fuel value for diabetics than the other food elements, and besides it is the only one which does not influence the quantity of urinary glucose. It would seem on this account to be the ideal food for persons suffering from a disease accompanied by progressive emaciation. Fortunately diabetics assimilate fats well, especially those of low melting power, such as butter, cream, etc., and those of vegetable origin, such as olive oil and that derived from nuts. They must be employed cautiously, for overindulgence may be followed by intestinal putrefaction with the well-known symptoms accompanying this state, or by fatty diarrhea, gastric disturbances, dealkalinization of the blood, or fatty infiltrations. As generators of energy or body force, their nutritive value is about twice that of carbohydrates and of proteids. Unlike proteids they are completely burned up during metabolism.

Fats are especially indicated in the more serious cases. I refer to those subjects who excrete glucose even on a carbohydrate-free diet, and who exhibit the ravages of the disease by the gradual disappearance of the subcutaneous and adipose tissue and finally of the musculature. Here loss of weight and waste should be balanced by an increased supply of fuel; fats such as are contained in butter, cream, or meats are indicated. Likewise soups, cheese, oily nuts, fried meats, bone-marrow, codliver oil, eggs, salads with oily dressing, and edible oils. Recent investigations indicate that fats are largely concerned in the production of the acetone bodies, and further that this property is possessed by different fats in different degrees. The higher fats, palmatin, and stearin, it seems, are less prone to cause an acid intoxication than the lower fats such as olein and butyric acid. One observer declares that the acetone group could be suppressed by the employment of fats in the form of bacon, but that butter promotes their appearance. If this theory could be substantiated, namely, that certain fats suppress the formation of the urinary acetones, its clinical significance would be most important. It would mean that the danger of an acid-intoxication could be minimized. I purposely use the expression "acid-intoxication" in lieu of "coma" for the reason that it has always been a question in my mind to what extent this phenomenon could be held responsible for the coma of diabetics. It seems by common consent to have been accepted as an explanation for this fatal type of coma, but it cannot be regarded as established until certain clinical facts and pathological findings are better understood.

In a previous paper I made the statement that "We cannot logically accept the acid theory of coma until certain apparently contradictory events in diabetism are reconciled." I made that claim three years ago, and to-day in the light of more recent investigations I am more emphatic in that belief. The theory of the origin of diabetic coma that would more completely harmonize with the clinical picture and with the physiological data would be, to my mind, one based on the recognition of endogenous toxins formed somewhere along the intestinal canal, subsequently finding their way into the general circulation, then causing paralysis of the nerve-centers. Clinically, I have had evidence of this sequence of events in not a few cases; notably those diabetics who suffer from surgical diseases, such as carbuncle or gangrene, or who have submitted to surgical operations. Other evidence is the frequency with which the coma is preceded by gastroenteric phenomena. It seems to me that when the formation and elimination of the waste-products of nitrogenous metabolism are better understood and ready methods for their detection discovered, we shall be many steps nearer the solution of the problem of diabetic coma.

The investigations of Knoop of Strassburg have established the fact that the acetone bodies result from the metabolism of both proteids and fats, and

that the most probable method is through the oxidation of the fatty acids. The researches of Embden and of Baer and Bloom, cited by Folin,[3] make it appear that those fatty acids which contain an odd number of carbon atoms may become converted during assimilation into β-oxybutyric acid, which is the mother substance of the other acetone bodies, and the agent directly responsible for the presumable blood acidosis.

While fats and oils take first rank as sources of energy and heat, they must be administered slowly to the diabetic. A quantity should be allowed to satisfy the requirements of the normal organism plus the energy lost through glucose excretion.

Besides the danger of a one-sided diet, I have alluded to that of under-feeding. I think I am on safe grounds when I make the declaration that many physicians are starving their diabetics; the treatment practically amounts to a scientific inanition in which the patient innocently acquiesces. In many instances instead of supplying food of sufficient quantity and of definite quality to maintain a physiological equilibrium and to allow for waste and repair of tissue, the diabetic is allowed to consume himself. This statement especially applies to those diabetics with large excretion of acetones accompanied by a progressive emaciation. Such patients are too often the victims of a too rigid exclusion of carbohydrates. To require a diabetic to live on two elements of food to the exclusion of the third means consigning him to live on his own flesh and blood, in other words at the expense of his own body. Healthy assimilation and repair cannot long proceed in such a way; emaciation must ensue, and with it a diminution in the functionating power of all organs involved in catabolism.

As far as concerns the dietetic treatment, we should not lose sight of the one cardinal fact, that total or partial failure to assimilate carbohydrates is the salient phenomenon of the disease. The principle involved in the treatment, then, must be to lessen the carbohydrates in the food, until the sugar disappears, if that is possible, and afterwards tentatively to replace them, noting the effects of each addition on the urine, as a guide to future dietary measures. In order to carry this principle into effect it is necessary to ascertain experimentally the patient's ability to assimilate carbohydrates. For purposes of estimating, approximately of course, this tolerance, several methods are employed, the most familiar of which is that known as "von Noorden's standard test-diet." This diet consists of three meals, carried out for one or two days, of articles free from carbohydrates, except that a measured quantity of bread is allowed for breakfast and lunch. The urine of the next twenty-four hours is collected, that of the day in a separate vessel from that of the night, and examined quantitatively for glucose, acetone, urea, and other ingredients. Both the percentage of sugar and the amount daily excreted are noted and cases classified as slight, moderately severe, and grave, according to their degree of toleration. To the first class belong those diabetics in whom the excretion of glucose is arrested on a starch-free diet. To the second class, the moderately severe, belong those diabetics in whom the excretion of sugar is not completely arrested, but markedly diminished on a rigid starch-free diet. To the third class, the grave cases, belong those diabetics in whom the excretion of glucose is not even diminished on a rigid starch-free diet. In this last group of cases sugar is formed from the proteid food elements.

The method I usually employ for the toleration test is the following: On the test day three meals consisting entirely of proteids, fats, and water are given, but between breakfast and the midday meal, the patient is told to drink a mixture of 50 c.c. of glucose dissolved in 250 c.c. of water. The urine of the next twenty-four hours is examined quantitatively.

Experiments conducted along these lines will disclose some interesting individual peculiarities. Foremost it will be demonstrated that the tolerance for carbohydrates is relatively represented by a quantity which varies within wide limits in different subjects and at various times. Again it will be found that the same subject reacts differently to various carbohydrates, nor does the same carbohydrate article, be it a cereal, or bread, or potato, or alcoholic beverage, affect the diabetic system always the same way; this phenomenon it appears does not depend upon the chemical constituents of the food but rather upon the pathological state of the patient. Another fact brought out prominently in these test-meal experiments, is that this carbohydrate potentiality can often be developed to such a degree that diabetics whose capacity was at first almost *nil*, will under suitable regimen, exhibit a moderate capacity to metabolize starches. In other words we can train the system to digest sugars, just as in infantile life the digestive organs are trained, step by step, to digest proteids. Reasoning analogously, I think it could be proven, if the matter were to be investigated, that the tolerating point for proteids and fats fluctuates in certain diseases of the liver, the pancreas, and of the intestines, and is rarely a constant function.

Having ascertained the point of tolerance, the diet in individual cases will shape itself accordingly. If the examination of the urine makes it appear that the patient's tolerance is amenable to a selected diet, too great rigidity should not be insisted upon; on the contrary a slightly larger quantity of starches should be allowed than can be assimilated, care being taken that the overproduction of sugar does not exceed a one or two per cent. limit. Of course this principle of dietary treatment presupposes a working knowledge of the percentage-contents of starchy foods, the method of their preparation, and their fuel values. Incidental to this method of treatment, it will be advantageous to place the patient upon an exclusive proteid and fat diet for several days every month in order to ascertain to what extent the excretion of sugar can be controlled and to purge the system of the redundant glucose. These periods of starch-abstinence at regular intervals exert a good influence toward increasing the power of assimilation and maintaining nutrition. Experience has shown that the capacity for sugars grows less and less the longer the diet remains unrestricted, while such evidences of the disease as ulcerations, skin manifestations, pruritus and thirst are directly due to the excess of glucose in the blood.

From a dietary point of view diabetics may be divided into two classes; those with slight disturbances of nutrition, and those with marked disturbances of nutrition.

To the first class belong those whose nitrogenous balance is undisturbed, but who have lost to some extent the power of metabolizing starches. These cases are amenable to diet. Considerable dietary laxity may be permitted under proper surveillance. The second class, those with marked nutritional disturbances, an excretion of glucose even on a starch-free diet, and rapid loss of weight, require all types of the food-elements—proteids to repair waste, fats to supply heat and energy, carbohydrates in quanti-

ties to sustain a normal blood alkalinity, and alcohol as a force-producer on account of its easy absorption.

Regarding the various so-called "diet-cures," such as the oatmeal, the potato, the skimmed milk cures and a host of others, I must record myself as having little faith in their value, despite the extravagant claims of the authors. When I read of cases that defied all treatment but showed marked and rapid improvement on potatoes or oatmeal gruel, it seems to me that the general restrictions of diet, that forms a part of these methods, were mainly responsible for the diminution of the glycosuria. Take the potato cure of Mossé for example; the latter claims that the beneficial results of potatoes are due to their large quantity of the potash salts, yet I have employed potash salts *per se* in selected cases without ever noting any improvement. It seems a contradiction to speak of any article of food as a specific when the whole range of therapeutic resources has been well-nigh exhausted in the search for a remedial agent.

A word regarding recent efforts to compute numerically the fuel values of the food elements, and to employ these coefficients in feeding diabetics. An ingenious theory of feeding patients upon the basis of calories has been elaborated, but as was to be expected, the results of the practical application of this method were disappointing. My own experience was that patients would always balk at this method of feeding. The caloric theory, although more or less convincing, has not yet arrived at a stage where it is possible to make a mathematical problem of the functions of digestion. Such a unit of value is empirical and arbitrary at the outset and does not take into consideration the disturbing influences of age, sex, habit, occupation, severity of the disease or its complications. It ignores the fact that the human machinery may be so out of gear, during disease, as to upset all our calculations, nor is there any assurance that the food doled out in measured quantities will go right to the spot unaffected by the morbid state of digestion.

You cannot calculate the wants of the economy with mathematical precision and you cannot make an algebraic equation out of the stomach and its functions. It might be done with large bodies of men in health, but not with individuals in disease.

The feeding of diabetic patients to-day permits of considerable latitude as to choice of articles; a fact which is in marked contrast to the privations insisted upon in former years. When the methods of testing for urinary constituents are simplified and made available for clinical purposes, we shall have more reliable means of prescribing a diet for diabetic sufferers. It is to physiological chemistry that we must look for great things; both pathology and bacteriology are even to-day of inferior importance.

Infant Feeding in the English Slums.—How some mothers in factory districts feed their babies was related by a medical man at a meeting of the Ancoats Healthy Homes Society the other day. He said: "I was called to see a sick baby, and found the mother feeding it with pieces of corned beef. When I told her not to give the baby that kind of stuff she replied: 'Well, sir, what am I to feed him on? He doesn't like pork'!"—*Medical Times and Hospital Gazette.*

SPONTANEOUS GANGRENE OF THE FOOT DUE TO ENDARTERITIS OBLITERANS.*

BY ISAAC LEVIN, M.D.,

NEW YORK.

GANGRENE or local death of any part of an organism is always due to a loss of the supply of blood, caused by some obstruction in the main artery of the region. The artery itself may be normal; and then the obstruction may be due either to an embolus carried over with the stream of blood, as in gangrene in patients with a lesion of the heart or aneurysms, or else to an abnormal contraction of the muscular layer of the arterial wall, caused by some abnormality of the vasoconstrictor nerves, as in gangrene in Raynaud's disease.

If the walls of the artery are diseased, then the obstruction is due either to progressive narrowing of the lumen by the proliferative inflammatory process or else to a thrombus which forms on the inner surface of the diseased wall.

Recent investigations have shown that arteriosclerosis is not necessarily a general disease, but that the blood-vessels of certain organs (brain, lungs, stomach) may be diseased, while the circulatory system of the entire organism may be normal.

Senile gangrene of the foot, or gangrene in the course of diabetes or acute infectious diseases (typhoid, typhus, scarlet fever, etc.) usually occurs in patients whose whole circulatory system is more or less involved in the disease process, but the so-called spontaneous gangrene of the foot, due to arteritis obliterans usually attacks young people whose arterial system is perfectly normal.

The disease does not occur frequently. Wartburg[1] in his report of fifty-two cases of spontaneous gangrene of the extremities, due to different causes, mentions only three cases due to endarteritis obliterans. It ought to be stated here that while some writers use the name spontaneous for every gangrene, unless due to trauma, frost-bite or other extraneous causes, others again mean by a spontaneous gangrene only gangrene due to endarteritis obliterans.

The cases reported so far differ widely as to the etiology and the anatomical appearance of the involved vessels, and consequently as to the interpretation given by the author. Every new case occurring in practice ought to be investigated so that more light may be thrown on the etiology and pathogenesis of this obscure disease.

The case that is to be reported here presents anatomically certain deviations from the general appearance of these cases, which seem to indicate the right pathogenesis of the disease.

The patient, Mr. L., thirty-five years of age, came to me complaining of severe pain in the right big toe and leg, lasting for about eight weeks. On examination I found the patient poorly nourished and anemic. The right leg and foot were paler than the left and cold and clammy to the touch. There was a small gangrenous spot on the inner surface of the nail phalanx of the big toe. No pulsation in the arteris dorsalis pedis or tibialis postica; faint pulsation at the upper section of the popliteal. Otherwise the patient had no organic disease, no heart lesion, tuberculosis, Bright's disease, diabetes, congenital or acquired syphilis, and no indication of general arteriosclerosis. I made a diagnosis of spontaneous gangrene due to endar-

*Presented in brief at the New York Pathological Society, January 15, 1908.

teritis obliterans and advised amputation at the knee joint. At the urgent request of the patient I amputated first the toe. Gangrene developed on the line of incision, and two weeks later I amputated the leg at the knee joint. The patient made an uneventful recovery.

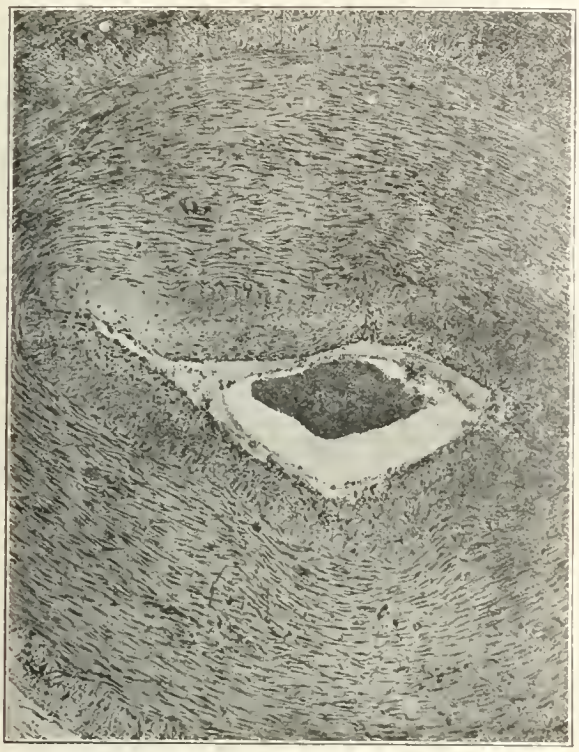

Fig. 1.—Wall of an artery; muscularis thickened.

On gross examination all the arteries of the leg appeared very hard and unelastic. Microscopical sections were taken both from the upper part of the tibial artery and from the stump of the toe. I take here the opportunity to thank Dr. J. H. Larkin for his help in the preparation of these specimens. Study of the specimens reveals the following condition: The walls of all the arteries as well as of the veins are greatly thickened. This thickening is due mainly to the middle muscular coat. The intima is only occasionally found thickened, usually in the vessels of very small caliber, and this thickening is insignificant in comparison with the thickening of the muscularis. The lumen of the vessels, while always diminished, is completely occluded only in vessels of small caliber. Both the tibialis and dorsalis pedis are patent. Most of the veins contain organized or unorganized thrombi; but there is no thrombus formation in the arteries. There was also noticed connective tissue formation in the sheaths and the intrafascicular bands of the nerve fibers.

The microscopical picture of the blood-vessels in this case differs in many respects from those found by other observers. But there is generally no apparent uniformity in the anatomical condition underlying the disease, if the different descriptions found in the literature are studied separately. Winiwarter[2] and Borchard[3] consider the condition mainly a thickening of the intima, which obstructs the lumen of the main artery and produces gangrene. Zoege v. Manteuffel,[4] Weiss[5] and Bunge[6] hold that in this affliction the intima becomes diseased, and on the diseased endothelium there forms a thrombus which obstructs the artery and produces gangrene. According to their opinion the lumen of the vessels can never become occluded by the thickening of the wall of the vessels alone without the formation of a thrombus. Haga[7] describes cases both with and without thrombi. Wulff[8] and Sternberg[9] both report cases which presented microscopically the identical appearance with the case reported here. The most important factor in the narrowing of the lumen of the vessels was the hypertrophy of the muscularis, while the growth of the intima was comparatively slight.

When the same disease clinically presents such apparently different anatomical pictures in different cases, the question must immediately arise, whether these different pictures do not simply represent different stages of the same disease. Wiedenmann[10] explains the progress of the disease in the following way: First, the lumen of the artery is narrowed; subsequent to this stasis forms in the circulation of the capillaries and veins; then the stasis causes formation of thrombi in the veins, and then only thrombi form in the arteries. This explanation certainly has the merit of unifying in a way the different anatomical pictures found by different observers. But it is still easier to correlate all the different anatomical conditions when one takes into consideration the following two facts: First, Wwedensky[11] in his very painstaking studies, came to the conclusion that changes in the blood-vessels are always preceded by disease of the nerve apparatus of the extremity. This opinion is of great importance, as it embraces the investigation of a number of cases. Most of the other observers did not examine the nervous system. In my case, as was stated above, there was found a connective tissue proliferation around the nerve fibers. The other fact to be considered before we

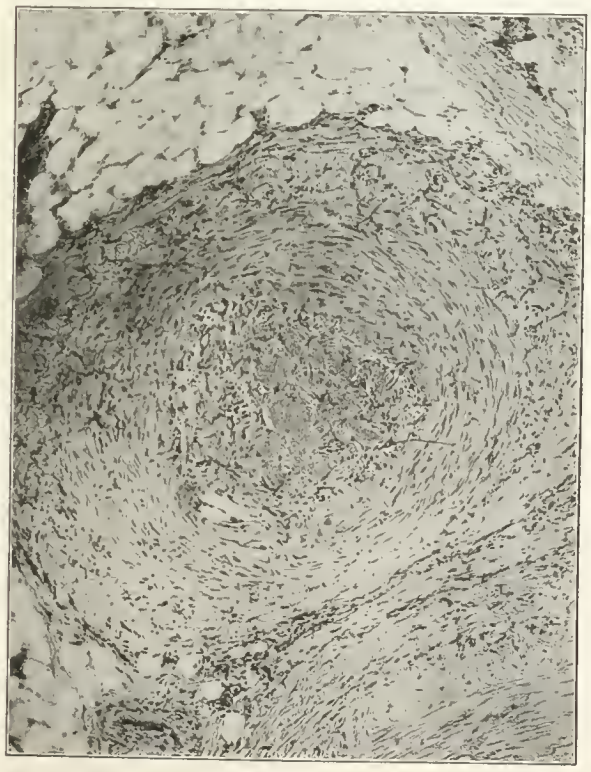

Fig. 2.—Wall of a vein; organized thrombus.

undertake the analysis of the microscopical pictures described, is the close clinical relationship between the spontaneous gangrene due to arteritis obliterans, the so-called "intermittent claudication" and Raynaud's disease. The main clinical symptoms of the latter disease described first by Rey-

naud[12] in 1862, consist in vasomotor disturbances and local pain, which may last for years before gangrene forms. The most characteristic feature of Raynaud's disease is that, even when gangrene is present, absolutely no anatomical lesion can be shown in the walls of the blood-vessels. As Hugo Strauss[13] states, the gangrene is caused either by *spastic ischemia,* with subsequent death of tissue due to lack of food, or by *spastic cyanosis,* with gangrene caused by autointoxication. In other words, the diseased nerves do not affect the tissue primarily, but contract the muscularis either of the arteries, and produce ischemia, or of the veins, with subsequent cyanosis.

Intermittent claudication, "intermittirendes Hinken" of the German authors, was first described by Charcot[14] in 1858. The name is derived from the fact that this disease, which mostly involves the lower extremities, is accompanied in its very early stages by an intermittent limp. The patient feels well, but after he walks a certain time the limb

Fig. 3.—A bundle of nerve fibers; a great deal of connective-tissue proliteration.

becomes painful and weak; he tries to protect it and limps. The same symptom is still more apparent in horses, who suffer very frequently from this disease.

Now intermittent claudication and spontaneous gangrene due to arteritis obliterans are practically the same disease, only in the former cases no gangrene has yet developed. The difference between both these conditions and Raynaud's disease lies in the fact that while in the latter there is no anatomical lesion in the blood-vessels, such lesions of one kind or another play the most important part in the pathogenesis of all cases of intermittent claudication or of spontaneous gangrene due to arteritis obliterans. Clinically it is not always possible to differentiate these conditions. While intermittent claudication occurs usually in the lower extremities, cases have been described where it involved the upper extremities, and lately a very similar condition with endarteritis of the arteries was noticed in the abdomen (Das arteriosklerotische Leibweh—Buch[15]; l'Arteriosclérose intestinale—Cheinisse[16]). The absence of pulsation in the corresponding artery is pathognomonic for the disease, but on one hand there are positive cases of intermittent claudication with the pulsation present, and, on the other, in cases of true Reynaud's disease, pulsation may disappear temporarily. It is also not always possible to determine by touch whether a certain artery is sclerotic or normal.

The following case illustrates these difficulties:

Mrs. S., aged twenty years, married, born in Russian Poland, came to me with complaints of constant pain in the middle finger of the left hand, lasting for a year and a half. The pain is severer when she goes out in the cold and also on nervous excitement. Six months ago the finger was cyanotic for about six hours, and then edematous for the rest of the day. The next day it became normal. Pulsation present; arteries do not feel abnormal on touch. She has no general arteriosclerosis, no syphilis or other constitutional disease, no disease in the bones or joints or any other part of the finger. The pain does not increase on pressure. While this case is certainly one of arterial disease, it is impossible to say whether it is the beginning of Raynaud's or intermittent claudication.

But the question arises whether there is really such a qualitative difference between these various groups, or whether they simply represent different stages in the same disease.

Such a close relationship between these different groups of disease would be very easy to detect, if one accepts with Wwedensky the lesion of the nervous system as a primary pathogenetic factor. Should the diseased part be the vasoconstrictor fibers of the vasomotor nerves, then the first effect on the blood-vessels would be a narrowing of the lumen through a spastic contraction of the muscularis, a condition we meet in Raynaud's disease. Such a continuous spasm would be followed by hypertrophy of the muscularis as described in this article and by Wulff and Sternberg. On the other hand, a spasm of the muscularis through interference with the circulation of the vasa vasorum may interfere with the normal nutrition of the walls of the vessels and produce both proliferative and degenerative changes in the intima. Whatever the reason for the narrowing of the lumen of the artery —spasm or hypertrophy of the muscularis or fibrous proliferation of the intima—there will develop to the periphery of the narrowed place a stasis with subsequent thrombus in the veins. The thrombi met with in the arteries either may be secondary to a complete stasis produced by a venous thrombus, as Wiedenmann describes it, or else the arterial thrombus may be formed in the artery, secondary to a degenerative process in the endothelium. It is self-evident that gangrene may be caused by any of these processes obstructing the lumen of the artery from a plain spasm to a thrombus. It may be interesting to mention here that Carrel and Guthrie[17] in their research on experimental arteriosclerosis also noticed, as one of the first conditions, hypertrophy of the muscularis.

As to the etiological moment producing the disease, there is no uniformity of opinion, nor are we able to indicate any one factor as playing the most important role. Haga[17] thinks that the disease is due to syphilis only. Zoege v. Manteuffel considers the most important factor to be *cold,* and ascribes the prevalence of the disease among Russians to the fact that they live in a cold climate. Erb[18] in studying a great number of these cases

came to the conclusion that while very little importance ought to be ascribed to syphilis, alcohol or cold, the excessive use of tobacco is the real etiological moment. But there are certainly cases of the disease where tobacco was used in moderation or not used at all. Oppenheim[19] and Goldflam[20] seem to lay a great weight on the nervous disposition of the patients, but, as Erb rightly remarks, the prevalence of men speaks against this reason. Most probably in different cases there act different combinations of different etiological factors. In the case reported here there was probably a combination of general malnutrition, overwork of the limbs (a great deal of walking), cold (a damp place of business), and some excess in the use of tobacco.

The treatment of these cases ought to be preventative, *i. e.* before gangrene develops. This should consist in removing the use of alcohol and tobacco and further in improving the general nutrition and the circulation of the limb, without doing anything which overexerts the muscles, like strong massage. If gangrene develops and we do not find any pulsation in the tibial artery, then Zoege v. Manteubel is right in stating that nothing short of an amputation at the knee joint will arrest the process.

While spontaneous gangrene of the foot, due to obliterative arteritis is a rare disease, it would be well for physicians to bear it in mind and, when a patient comes complaining of a constant pain in a toe or finger or even an occasional painful cramp in the muscles of a leg, to examine the arteries of the extremity. It is also well to keep this disease in mind while treating cases of diabetes and senile arteriosclerosis; with proper care an occasional case of gangrene may be prevented from forming.

So-called Temperance Beverages.—The British Government analyses show a very high percentage of alcohol in many of the favorite beverages of teetotalers. The law makes drinks containing more than 2 per cent. of alcohol taxable as intoxicants, but most of the samples examined contained more than this amount, sometimes as much as 10 to 12 per cent. Ginger beer and herb beer were the worst offenders, but one preparation called dandelion stout contained 12.3 per cent. of alcohol.

THE RELATION OF APPENDICITIS TO GYNECOLOGICAL PELVIC DISEASES.*

By SAMUEL WYLLIS BANDLER, M.D.,

NEW YORK.

ADJUNCT-PROFESSOR OF GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

There are conditions occurring in the right lower quadrant of the female abdomen which at times so simulate each other as to symptomatology that, in the early stages especially, a differential diagnosis is sometimes difficult. Certain cases of ectopic gestation and of ovarian cysts with twisted pedicle may render a differential diagnosis from appendicitis necessary, but the most frequent conditions in which doubt exists are acute, subacute, and chronic appendicitis as distinguished from acute, subacute, and chronic inflammatory diseases of the adnexa. In so far as the appendix and, in part, the adnexa are covered by peritoneum any infection of the peritoneum may involve both of these structures. For the very same reasons the element of physical contact comes into play. There are instances of inflammatory involvement of the appendix, in which the structure is so situated that it becomes attached to the uterus, the tube, or the ovary. There are, on the other hand, conditions involving the tube and ovary and even the uterus, in which adhesion of an uninflamed appendix to these structures results. The element of situation not alone brings these two structures into relation, but makes the differential diagnosis at times difficult.

There are cases of acute gonorrheal involvement of the tube with more or less extensive peritonitis in which the differential diagnosis from appendicitis is not made. Instance the case of a patient married only five weeks, suddenly attacked with pelvic pain and diagnosed as appendicitis. Having been made cautious by previous experience, a vaginal examination was made, and this plus the use of the microscope resulted in the diagnosis of double pyosalpinx due to gonococci, which diagnosis was readily verified by questioning the husband. Operation showed the omentum adherent to the right tube at the uterine horn and some of the epiploic appendages of the sigmoid adherent to the left tube, near the uterine horn. The intestines were not markedly injected. Both tubes were the size of the little finger at the uterine horns and their outer ends were the size of the thumb, adherent to the posterior wall of the broad ligament and to the posterior wall of the ligamentum infundibulo-pelvicum. The broad ligament was not much thickened. During the enucleation of the left tube and ovary, pus poured out which was caught with sponges. The tube and ovary were very adherent. The ovary was hard, contained little cysts, but did not seem macroscopically to be infected with pus. The right tube and ovary were found relatively in the same position and were released from adhesions by finger dissection and brought out into the abdominal wound. The uterus was not congested nor red, but seemed large, looking like a pregnancy of about six or seven weeks. The appendix was red and congested. It was removed and the stump was buried. Before completing the operation adhesions of the sigmoid to the lower half of the uterus were loosened by blunt dissection by the fingers which left a rough denuded area of peritoneum about two and one-half inches long and one inch wide. This

*Read as part of a Symposium at a meeting of the East Side Physicians' Association.

was closed by six interrupted sutures. The pus was examined and gonococci were found.

Now cases of this acute nature, and especially cases of a subacute nature, may result in such a situation of the adnexa of the right side that only operation can definitely settle the original site of the inflammation, as is evidenced by the following case. Diagnosis: Retroflexio-versio fixata, pyosalpingitis with adhesions on both sides and high up. Because of the fixed uterus, because of its high position, because of the high lateral situation of the fixed tubes and ovaries, an abdominal operation was done. The uterus found in fixed retroflexio-versio, adherent to the sigmoid, the upper part of which was firmly adherent to the right pelvic brim at the situation of the ligamentum infundibulo-pelvicum. With the hand the left tube and ovary were loosened from their adhesions to the posterior wall of the broad ligament and to the postero-lateral wall of the pelvis, just below the ligamentum infundibulo-pelvicum. The uterus was then grasped with a volsellum. It was impossible to pull it up in the wound because of the short right broad ligament. The adhesions were separated on the posterior wall of the uterus to the sigmoid; they were thick, infiltrated, and brittle and bled readily. The right tube and ovary were not adherent to the posterior wall of the broad ligament. By following the course of the tube it was found that the ovary was attached to the brim of the pelvis about an inch below the appendix and that it was covered by the sigmoid flexure. Epiploic appendages completely covered these adhesions of the sigmoid. The sigmoid was loosened with the finger and then the ovary was dissected out by passing the finger around and underneath it, after which it was freed from its attachment to the posterior wall of the ligamentum infundibulo-pelvicum. The appendix, which was long, thick, infiltrated, and covered with adhesions, was then removed.

So far as the appendix with its peritoneal covering is concerned, it is perfectly natural, as we have seen, to expect that inflammatory involvement of the adnexa with which a peritonitis is associated, may by contact or direct continuity involve the appendix together with other intestinal structures in peritoneal adhesions.

An imporant question is: Do milder inflammatory diseases of the adnexa cause appendicitis? Continuing out from the broad ligament along its upper border and extending to the lateral wall of the pelvis and running up practically to the base of the appendix, is situated the right ligamentum infundibulo-pelvicum. This structure as well as the broad ligament is rich in lymphatics and it has been stated that involvement of the adnexa may permit an extension of bacteria through these lymphatics up to and involving the appendix. While this opinion has been expressed by more than one observer it must be remembered that appendicitis is an affection which occurs from the lumen of that structure and that bacteria passing up through these lymphatics, while they might cause infiltration or induration about the cecum, are not responsible for the occurrence of acute or subacute appendicitis. Those men who make it a routine practice to remove the appendix in all abdominal gynecological operations are in a position to verify this assertion. I myself have never been able to observe an extension of disease occurring by this lymphatic path. I may state on the authority of Dr. Boldt, who has had dozens of such appendices examined, that inflammatory diseases of the right adnexa stand in absolutely no causal relation to the production of inflammatory involvements of the mucous membrane of the appendix. This point may be illustrated by the following case:

Diagnosis: Fixed retroversion, double salpingo-oophoritis with adhesions. History of abortion, followed some time later by a profuse yellowish cervical discharge. The left tube and ovary were situated rather high up. Abdominal operation was selected for this reason, and because of the probability of adhesions. The intestines were free everywhere, except for adhesions to the left ligamentum infundibulo-pelvicum. The broad ligament was thickened and both ligamenta infundibulo-pelvica were as thick as the little finger. The left tube and ovary were loosened from their adhesion to the posterior wall of the ligamentum infundibulo-pelvicum. The ovary was covered and bound down by numerous adhesions. The tube near the fundus contained a nodule the size of a hazelnut. Diagnosis was made of salpingitis isthmica nodosa. The tube was cut by a wedge-shaped incision out of the uterine horn. This incision was closed by four mattress sutures. The right tube and ovary were then freed from adhesions situated in relatively the same position. A special suture was placed around the ligamentum infundibulo-pelvicum. The right tube was found also to have a nodule in the same location about three-quarters of an inch from the uterine horn. The tube was cut out of the uterus by a wedge-shaped incision. The wedge-shaped incision was closed by three mattress sutures. A band of adhesions fully two and one-half inches long and one inch wide extended from the posterior wall of the left side of the uterus to the sigmoid. This were loosened from the uterus by blunt dissection and the cul-de-sac was then found free. The appendix was readily found by following the left ligamentum infundibulo-pelvicum upwards. The appendix, slightly congested and edematous, was removed. With this marked infiltration of the broad ligaments and the ligamenta infundibulo-pelvica no induration or infiltration was found about the cecum or appendix.

The question under discussion takes on quite a different phase when we consider diseases of the adnexa as possible sequelæ of appendicitis. Take for instance the question of tuberculosis. Tuberculosis of the tube and ovary may occur by upward extension of tubercle bacilli through the cervix, or tubercle bacilli may be deposited through the medium of the circulation, or tubercle bacilli may involve the tube and ovary subsequent to their presence in the peritoneal cavity. Whatever may be said as to the occurrence of such an infection through the first two channels, it is undoubtedly true that in the vast majority of instances tuberculous involvement of the appendages occur subsequent to the presence of tubercle bacilli in the peritoneal cavity, with or without macroscopic evidences of tuberculous peritonitis. The tubercle bacilli when present in the peritoneal plasma are carried into the tube lumen by the action of ciliated epithelium, and however much or little the peritoneal covering may be involved by tuberculosis, the lumen of one or both tubes is rarely free of tubercles. I had the opportunity on one occasion to make microscopic sections in a case of tuberculosis of the adnexa in which the appendix was removed. The appendix on examination contained tubercles and giant cells, and they were not present on the peritoneal surface, but were present in the structure and lumen of the tube so that the tuberculous ap-

pendicitis was part of the primary condition and the tuberculous adnexitis was secondary.

Now, as to the question of appendicitis. When an involvement of the appendix takes place and there occurs an associated peritonitis more or less localized or more or less diffuse, we are dealing principally with streptococci or bacteria coli in the peritoneal exudation. This exudation need not be great or extensive, it need not extend down deep into the pelvis. It may be slight and localized immediately around the appendix, for the action of the ciliated epithelium in the tubes attracts towards the adnexa and takes up into the tube lumen these infecting bacteria. Here we have the possibility of an involvement of the peritoneal covering of the tubes and especially the possibility of an involvement of the ovary and its Grafian follicles.

Personally, I have for a long time noted the occurrence of tubal and particularly ovarian involvements, generally infecting the right side, which occurred in patients in whom an infection from below could be almost excluded. In addition these involvements were not all of a nature which spoke for gonorrhea and the tube was generally open. They occurred in individuals at a period of life when the lesions could not be referred to the infectious diseases of childhood, and the history in many cases pointed distinctly to previous mild or more severe involvements of the appendix. Thus, I came to the conclusion that the bacteria thrown out in the peritoneal exudation resulting from appendicitis produced an involvement of the uterine adnexa. This involvement naturally varies in different individuals, according to the susceptibility of the peritoneum to inflammation and adhesions, according to the virulence of the bacteria, the resistance of the patient and other factors which we are at present unable to determine distinctly.

It might be expected that evidences would be present in the genitourinary tract which could definitely settle for us in all cases the point from which the infection started; but we all know that, especially in subacute and chronic cases, evidences in the cervix and uterus may be almost wanting and the point of origin is for that reason sometimes doubtful. The history of previous attacks does not give always a definite picture pointing clearly either to appendicitis or to infection of the adnexa, and only the evidences at the time of operation make the differentiation. I mention the case of a patient suffering for years from right-sided pain, in whom the diagnosis made by several men varied between salpingo-oophoritis, chronic appendicitis, and both. Vaginal examination showed a right salpingo-oophoritis, the adnexa were fixed high up on the posterior wall of the ligamentum latum. The appendix was sensitive and was diagnosed as involved with the right salpingo-oophoritis. The abdominal route was selected because of the involvement of the appendix and because of the desire to fix the uterus high up on the abdominal wall in case a conservative operation was indicated, and possibly to sew the ovary through a slit in the broad ligament to the anterior wall of the ligamentum latum. The right ovary was found enlarged and cystic, containing especially one very large Graafian follicle cyst. The tube was found closed and adherent. The outer half was resected and a large artificial abdominal end was made. Three-quarters of the ovary was resected and closed by interrupted catgut sutures, one mattress suture being placed across the hilus ovarii. Then the ligamentum infundibulo-pelvicum was shortened by the excision of a V-shaped piece, which, with the shortening of the left ligament, left the uterus in a fairly good position. The appendix was found enlarged and bound down by numerous adhesions about the mesoappendix. It was removed. A ventral suspension was done.

The form of pelvic disease very frequently resulting from appendicitis is shown by the following case. Diagnosis: Double salpingo-oophoritis without adhesions; uterus in normal anteflexion. Operation done for pelvic pain. Both tubes were found somewhat congested, but the outer ends were open. The broad ligaments were extremely varicose. The right ovary was enlarged and full of small cysts with very thin coats. Three-quarters of this ovary was resected and closed with interrupted catgut sutures. The left ovary seemed fairly normal but contained many small cysts. It was left in place. The appendix was then looked for and was found at the normal situation. It appeared like a lump the size of a small walnut and perfectly round, with the exception that it had a base which ran into the cecum. It looked more like a gland than an appendix. By cutting the peritoneum along its median margin and by dissecting this back with gauze it was found to be a thick appendix the size of a lead pencil, extremely hard and firm, doubled on itself, and firmly adherent. With the scissors the united sides were separated, whereupon the lining mucosa was exposed, but the lumen was not cut into. The appendix then appeared to be about two inches long, extremely hard, especially at the base, which seemed to project into the intestine, making a mass within the intestine about the size of a hickory nut. The appendix was cut off close to the base and inverted by peritoneal suture in the cecum. Three other interrupted sutures were passed over this, closing the appendix area very thoroughly. Practically no mesoappendix existed, but a bleeding artery was exposed which was tied by a ligature.

After observing many cases in which this causative appendicitis explained for me certain milder involvements of the tube, and especially cystic changes in the ovary, I finally chanced upon the following unusual case: Diagnosis of right ovarian cyst. Abdominal operation was done because the patient was a nullipara, because the cystic tumor, the size of an orange, was fixed laterally to the pelvic wall, and because the left ovary was likewise fixed laterally to the pelvic wall. On opening the abdomen, the omentum was found fixed to the anterior abdominal wall to the right of the line of incision. The omentum was found adherent to the right horn of the uterus, to the right side of the bladder, to the anterior abdominal wall, and to the ligamentum infundibulo-pelvicum on the right side. It completely walled off the appendix and the right tube and the ovary from the general peritoneal cavity. No other adhesions were found here, but later the left tube and ovary were found bound down and covered by loose, very thin, and stretchable adhesions. The omentum was tied, cut, and pushed upward into the abdominal cavity. The right ovary was found adherent and contained one large cyst the size of a very large egg. In loosening it from its adhesions the cyst broke and a clear fluid flowed out, leaving the ovary still the size of an egg. The tube was not thickened or infiltrated. The adhesions to the ligamentum infundibulo-pelvicum and the posterior wall of the ligamentum latum were loosened. Two ligatures were placed around the ligamentum infundibulo-pelvicum and two mass sutures from the middle of the broad ligament were tied to either side of the tumor, an extra suture be-

ing placed at the uterine horn after the tube was cut out. The tumor was then removed. The other tube and ovary were brought out from their adhesions, and the adhesions between the tube and the ovary were loosened. The abdominal end was found open. One-half of the ovary which was cystic was resected and closed with interrupted sutures.

In the course of this operation I expressed the opinion that the inflammation was not gonorrheal because of the character of the adhesions, because the tubes were not infiltrated, and because the tube ends were open. The opinion was expressed that the adhesions were probably subsequent to an appendicitis. The cecum was then drawn out and numerous long, flat, thin, web-like adhesions were found. The appendix was one and a half inches long and was separated completely for the space of one inch from the cecum. The blunt separated end was connected with the cecum by adhesions of the same sort as were present about the appendix. The appendix and its mesoappendix were tied and cut through the adhesions connecting the blunt end with the cecum. Here the appendicitis had caused a spontaneous amputation of the appendix and had produced the associated pelvic peritonitis.

The form of pelvic disease most frequently resulting from mild appendicitis is not associated with adhesions of the adnexa. The broad ligament or ligaments are varicose and the ovary is cystic. The appendix shows constrictions or adhesions.

Pain in the right or left sides or both sides, but especially in the right side, is frequently due to a structural involvement of the ovarian tissue without the presence of adhesions or closure of the tubes. With this is very frequently associated a varicose condition of one or both broad ligaments or a shortening of one or both ligamenta infundibulo-pelvica. This condition of varicose veins of the broad ligament may be due to thrombotic or other changes subsequent to curettage or to mild and often unrecognized infections extending into the parametrium from the cervix or uterus, post partum or after abortion. These may be responsible, through circulatory and inflammatory disturbances, for changes in the structure of the ovary and for the production of small cystic degeneration or cirrhosis. It is certain that appendicitis too may cause such a change in the broad ligament and may produce inflammatory changes in the ovary. These are often found on the right side combined with a special symptomatology and with a shortened ligamentum infundibulo-pelvicum. This pathological involvement of the ovary and broad ligament of the right side is often noted at operation to be associated with involvement of the appendix and the mesoappendix. The ovary may be altered in size and contain cysts. The tunica albuginea may be thickened and the stroma may be indurated so that the term cirrhotic ovary seems justified occasionally. The characteristics of this ovarian involvement are not modified greatly by the symptoms of involvement of the appendix. So far as the ovary is concerned, there is a steady, gnawing, burning pain, which often radiates into the thigh or extends upwards towards the ribs or which may be felt in the iliac bone. The pain is more noticeable after walking or on exertion, and is therefore most marked at night. During the week preceding menstruation it increases in intensity and on the establishment of menstruation it may grow less or it may continue. An associated annoyance is nausea which may be felt before, during, or after menstruation. The pain felt in the ovarian region may, at some menstrual periods be marked, at other periods less severe. The reason for these symptoms can be readily understood. We are dealing with an ovary altered in structure, and with a varicose broad ligament. Menstrual congestion produces a hyperemia in these structures, and pain is therefore increased during the premenstrual period. If a follicle ripens in the involved ovary, the pain is more severe. If the tunica is thickened, the rupture of the follicle is prevented and the follicle increases in size. Rupture of the follicle eases the pain. Bimanual examination at an intermenstrual period may show nothing palpably except a sensitive ovary. It may, if frequently repeated, show the period of greatest pain to be associated with the presence of an enlarged ovary and an unruptured follicle. Women with these alterations may suffer for months and years with this almost constant, but not very severe pain, which eventually has a harmful and injurious effect on their physical and nervous state. Even though this ovarian pain is most frequent in women with a sensitive nervous system, and even though the pain is caused by the functional congestion of menstruation and by ovulation, nevertheless it is this function, carried out in an ovary altered even though slightly as to its stroma and tunica, which causes the local annoyance. Often enough there is associated a uterine displacement or enteroptosis or ren mobilis which are considered the cause of the pelvic annoyance. When these patients are finally reduced to a state of nervous and physical asthenia, the diagnosis varies from appendicitis, movable kidney, nephrolithiasis to neurasthenia and hysteria. A close study of the history of the case, of its development and of its course, shows the annoying symptoms to be related to the functional activity of the ovary. Sometimes these cases are correctly classed under ovarian dysmenorrhea. More often the appendix is removed through a small incision or an Alexander Adams operation is done or a movable kidney is fixed and naturally enough the symptoms continue. It is certain that predisposition to asthenia makes patients more sensitive to pain and that alterations in the ovary need not be marked to produce the symptoms mentioned above. On the other hand, the long duration of pain is sure to intensify the asthenia predisposition and may bring on a state of semi-invalidism.

Conclusions.—My conclusions are as follows: (1) Appendicitis in the form of an inflammation of the mucous membrane does not result from inflammatory diseases originating in the uterus or adnexa. (2) Involvement of the appendix viewed as a peritoneally covered organ may take place as part of a peritonitis, more or less localized or more or less extensive, which has its origin in inflammatory diseases of the adnexa. (3) Severe inflammations of the appendix, in so far as they cause a pelvic peritonitis or in so far as the accumulation of pus is located in the pelvis, naturally involve the uterus and adnexa in adhesions, do not cause pyosalpinx, but may cause tuboovarian cysts. (4) A differential diagnosis as to original site of the infection, when the appendix and right adnexa are involved, is often impossible except from the operative clinical standpoint and even then is not always certain. (5) Mild attacks of appendicitis, without the production of well defined peritonitis, may involve the adnexa without adhesions, but especially by infection of the Graffian follicles, alterations of the stroma and the production of varicocele of the broad ligament. (6) Such alterations in the ad-

nexa generally result from processes extending from the cervix and uterus into the broad ligaments and a definite decision as to the source of the trouble may be often impossible.

BLOOD-PRESSURE IN THE PRACTICE OF MEDICINE.

By W. FOREST DUTTON, M.D.,
PITTSBURG, PA.

Blood-pressure is the force exerted by the blood upon the cardiovascular walls. This pressure may be supernormal, normal, or subnormal. Any aberration of blood-pressure produces a pathological condition. Therefore, it will be necessary in taking up this subject to consider the various phenomena peculiar to this condition. Dr. Ludolf Krehl, of Strasburg, has made the following observations: stimulation of the peripheral nerves will normally cause reflex arterial contraction and rise of blood-pressure. Nervous impulses from the heart are able to affect the size of the blood-vessels and in a measure regulate the work of that organ. The degree of contraction is dependent on the impulses they receive. As the arteries leading to certain parts of the body dilate and contract, the blood supply to that part is altered." These observations are confirmed by some authorities and denied by others, so it leaves one to investigate for himself.

The study of blood-pressure in lower animals has been very unsatisfactory because of the low scale of the organism. Experiments on normal man have produced some good results, but the only reliable study of blood-pressure disease is the disease itself.

The pathology of abnormal blood-pressure will be dealt with summarily. Blood-pressure may be, primarily, the etiological factor, or, secondarily, the sequence of pathological conditions. When blood-pressure is the causative agent, it produces at first a hyperemia of the capillaries and arterioles, and causes a leakage into surrounding tissue. Long continued congestion of the capillaries results in capillary dilatation, capillary ectasis, or capillary aneurysm as shown in passive congestion of the lungs. Hyaline degeneration may be observed in the brain, kidneys, lymph glands, or tumors. Fatty changes in capillary epithelium occur frequently in various conditions. Hemorrhage may result from diapedesis or rhexis. These conditions also play a part in thrombosis and embolism. Calcareous infiltration occurs frequently, as observed in arteriosclerosis and its sequelæ. The calcareous infiltration may be preceded by amyloid degeneration, as found in the capillaries of the spleen, liver, kidneys, and in general amloidosis. The heart and arteries follow in various degenerations. These changes are fully discussed in ordinary textbooks on pathological anatomy, and I need not dwell on them here.

The etiological factors are: (1) Mechanical; (2) reflex; (3) central—in reference to the central nervous system.

Mechanical factors, such as inelasticity of the arteries, increased amount of blood, capillary congestion, impeded venous circulation, forcible action of the heart, muscular exertion, increased atmospheric pressure, cause increased peripheral resistance, or supernormal pressure. A softening or fatty condition of the arteries, diminished force or action of the heart, decreased amount of blood, and decreased atmospheric pressure produce subnormal pressure.

Reflex causes, such as stimuli direct to the vessel wall or heart wall and contained ganglia, produce at once a supernormal or subnormal pressure. The irritant may be adrenalin, nicotine, alcohol, lead, the nitrites, aconite, digitalis, or caffeine. Chemical and biological irritants are found in gout, chlorosis (von Noorden), autotoxemia, fevers, Bright's disease, and syphilis. Intense heat, electricity, and vibration are among other causes that may be classed reflex.

Central causes, or those due to influence on the central nervous system, such as worry, grief, joy, fear, produce at once vasoconstriction, or dilatation. "Stimulation of the central nervous system will stimulate vasomotor centers and thus produce contraction of the splanchnic vessels and great rise of blood-pressure" (Krehl). "Continuous high pressure may accompany renal disease, arteriosclerosis of the aorta or of the splanchnic vessels" (Krehl).

The symptoms of aberrated blood-pressure are varied and complex. They stimulate symptoms of other diseases and may partake of or complicate other diseases. The brain, because of its large blood supply, is generally the part first affected by the abnormal pressure and gives rise to headache, vertigo, syncopal attacks, disorders of vision and hearing, blunted intellect, irritable temper, and perhaps hallucinations or acute mania. The face and eyes may be red and congested, and the cartoid pulsating. The sleep is disturbed by dreams and cramps in the limbs. The patient has usually no complaints unless he is attacked suddenly by a sensation of falling and may stagger, if standing, and sink unconscious and completely relaxed to the ground.

The next to be affected, and perhaps the next to come to notice, is the heart. Uneasiness and precordial discomfort are ordinarily the first symptoms. Palpitation or pain is seldom complained of except when there is much increased demand on the heart. The general symptoms are, flushing of face, headache, carotid pulsation, tinnitus aurium. In the early stages of high blood-pressure, the first and second sounds of the heart may be metallic and accentuated. In the early stages of atheroma, the cardiac impulse is forcible and the second sound accentuated. The patient may be walking along the street, when he feels a peculiar heavy throb in the chest which is accompanied by a momentary sensation of choking or smothering. He feels everything give way under him, loses control of limbs, staggers, and by chance falls, at other times recovers before losing his balance. This is a condition which I shall call artery block, producing temporary or transient stoppage of the heart. This block, caused by spasm of capillaries, arterioles, arteries, and probably the heart, may be so forcible as to cause paralysis, rupture, or valvular lesion of the heart.

Following closely, or simultaneously, the kidneys, liver, and lymphatics are affected. When these organs are affected the blood-pressure is, at all times, abnormal unless regulated by treatment. The lungs are generally the last to be affected, except in tuberculosis, bronchial asthma, or cardiac asthma (Hare).

Diagnosis may be determined early by the characteristic variations of pressure. I have found in my own cases, using the Riva-Rocci sphygmomanometer, or the Cooke modification, that the physiological variation of blood-pressure is, when lying at rest:

For children of 1 to 5 years..	80 to 98 mm.
For children over 5 years...	98 to 112 mm.
For adult women.....	110 to 130 mm.
For adult men.....	120 to 140 mm.

I have used the sphygmograph a great deal for experimental purposes, but find it inconvenient for practical use, on account of the delicate mechanism. Otherwise the diagnosis is made only by close study of symptoms and sequelæ.

The prognosis is invariably good if the abnormal pressure is recognized early, and when not produced by degeneration of heart or vessels, or the presence of unconvertible substances in the blood. When aberrated pressure is associated with degenerative processes, the prognosis is fair, provided a compensatory metabolism exists or can be produced. In degeneration and noncompensatory conditions the prognosis is grave, though life may be prolonged by active and persistent treatment.

The peculiar psychic influence that governs us in modern society brings about various degenerations in the human organism. It is not the environment, but the many attributes due to heredity that influence one individual's thirst for alcohol, and another's desire for tobacco. The gourmand, whose features and organs are engorged by unassimilable material, loaded with poisons for the blood, possesses an organism which is at once abnormal. To change this order of things brings before us a most complex problem. Primarily, the individual must be warned of the dangers before him, and the necessity of seeking advice. Secondarily, the part of the clinician should be the early recognition and treatment of blood-pressure diseases.

The indications for treatment are, if the blood-pressure is supernormal, reduce to normal, if subnormal, raise to normal, and remove the cause of abnormal pressure whenever possible. Supernormal blood-pressure is best met by persistent use of tincture of veratrum viride, aconite or their alkaloids, in small frequently repeated dosage. The nitrites, atropine, and iodides combined with Fowler's solution, may be used with beneficial results, at the same time keeping the bowels, kidneys, and skin acting freely. The habits of the patient should be corrected. The patient should take light exercise in the fresh air before meals. The diet should be restricted, avoiding all forms of stimulants, meats, and the ingestion of large quantities of liquids.

Subnormal blood-pressure is met by adrenalin, alone or combined with physiological salt solution, ergot, suprarenal extract, hydrastinine hydrochlorate, digitalis, ammonia, camphor, alcohol, apocynum, strophanthin, caffeine, convalleria, physostigma, and strychnine. These drugs must be absolutely pure. They may be alone or combined as indicated.

A rigid hygienic system should be enforced. The patient should be given wholesome food, such as eggs, fresh meat, fish, milk, stewed fruits, vegetables, fats, and carbohydrates. He should have baths, plenty of rest, sunlight, and fresh air; should wear wool or silk and wool in all seasons. Patients fare better in rural and mountainous districts or at the seashore.

I have presented the treatment by drugs and diet in a cursory way that I might add suggestions which I consider most important in treatment of blood-pressure diseases. I have found most diseases affecting normal circulatory equilibrium due to foreign substances in the blood. These substances so disturb the vessel walls and nerve supply, that they not only interfere with anabolism, but produce marked catabolism of the entire organism. The irritant may be a chemical or an organic agent, such as lead, alcohol, nicotine, arsenic, mercury, phosphorus, the various gases, products of autointoxication, and food poisons. The most pronounced of the biological irritants are the *Spirochæta pallida*, bacillus of Eberth, diplococcus of cerebrospinal meningitis, bacillus of diphtheria, diplococcus of pneumonia, *Plasmodium malariæ*, bacillus of Pfeiffer, or their toxins. In uremic poisoning and eclampsia, the causes of which we do not exactly know, a regulation of the blood-pressure, blood quantity, and blood quality, ameliorates the diseases.

The use of electricity, light, heat, and hydrotherapy in blood-pressure diseases is to be encouraged.

The most valuable adjunct to medical treatment is venesection. In any hypernormal pressure, when immediate relief is needed, venesection should be resorted to. This relieves the intracardiac and intravascular pressure. The specific gravity of the blood is reduced, the amount of toxic or irritant material is lessened, engorgement of the lymphatics, and venous stasis, is relieved. The heart and vessels regain their equilibrium, and cell activity gives new life to the overworked organs. It may be remarked that this is a credible clinical picture. I call to mind a man who came of an apoplectic family. All were very stout. His brothers died at the average age of forty-five years. Being the youngest brother, he had opportunity to learn the prodromal symptoms of the disease. At the age of forty he began feeling the same symptoms as the brothers. He consulted a physician and was depleted of thirty ounces of blood. This he had repeated whenever he felt any return of the symptoms, sometimes as often as four or five times yearly. To-day he is living and well at the age of sixty-five. This man is one of many who have benefited by this so-called old and effete practice. In a paper on "Venesection; its Therapeutic Value," published in *Clinical Medicine*, for January, 1907, I have presented the technique and results in some 600 cases of various diseases. I do not wish to be misunderstood as heralding venesection as a panacea. I want to impress you with its value. There are thousands of deaths every year from apoplexy, heart, and other diseases, where medicine is practically inert, that may be prevented by timely venesection. It bridges the chasm of empiricism, affects suggestive consciousness of the patient, and gives time for therapeutic accuracy.

In a conversation on venesection, one of the foremost educators and medical authorities in America said, "I do not know much about the value of venesection, although I believe it is a good thing." This seems to be the status of the profession concerning the scientific application of venesection. This does not reflect on the individual physician, but it certainly casts a shadow over the teaching in our medical schools.

The object to be kept ever in view is the cause of the disease. This should be searched for carefully until found, and if not found, the disease must be treated symptomatically.

In the study of abnormal blood-pressure, we have the underlying cause or sequence of over half the human ills, which makes it one of the most profound subjects known to the science of medicine. Much is understood and much is misunderstood. I have proven by my own experiments and observations that the life of the human organism, whether through heredity or other causes prone to be aberrated blood-pressure, may be prolonged ten to twenty years. So long as normal blood-pressure can be maintained, the life of the organism will be sustained until the natural sequences of decay result in death.

HEALTH OF OUR HIGH SCHOOL CHILDREN.

By ELIZABETH JARRETT, M.D.,

NEW YORK.

MEDICAL EXAMINER TO THE BOARD OF EDUCATION.

In an article on the "Health of School Children" (*Outlook*, November 17, 1906), Mr. G. W. Wharton tells with great definiteness what is being done in New York by the Boards of Health and of Education, acting conjointly, to guard the well-being, physical and mental, or perhaps I might say, physical and therefore mental, of New York's great school population.

I was one of the first set of inspectors appointed by the Board of Health, and having worked in the schools for nearly six years, can testify to the rapid strides which that work has taken. For the past five years, however, my work as Examiner for the Board of Education has put me in close touch with the upper end of the line, so to speak, with the high school graduates and those who have finished their work in our two great public colleges, and it is of the health of these girls and boys, at the close of their twelve to fifteen years of school work, that I wish to speak, and incidentally sound a word of warning.

In my present work as Examiner, there come before me every year from eight to twelve hundred applicants, men and women, averaging from eighteen to twenty-five years of age. These one might call the finished product of our public school training, physical and intellectual. They are all candidates for some post in the public schools, either as elementary teacher, or in some special branch, such as cooking, physical culture, drawing, kindergarten, shop-work, etc. Of course, some of this vast number come from other States; some are considerably older than twenty-five, but for the purposes of this article the statement that the majority of them are under twenty-five and are the output of our New York City school system, will stand.

Under the present bylaws of the Board of Education, every candidate for the post of teacher in our public schools, in addition to the so-called written examination, which determines intellectual fitness, and the oral examination, which brings into prominence the personal equation, general bearing, self-control, power of language, etc., must also pass the physical examination. This examination aims to cut out those applicants afflicted with permanent incurable organic disease. Briefly, it includes an examination of eyes, ears, throat, heart, lungs, kidneys, as well as of the general nervous condition, and a statement as to the presence of any physical defect or deformity, from which the applicant may be suffering. The wisdom of this examination we will not now fully discuss. When I state that in the first year seven per cent. of all the applicants were rejected on the ground that they were likely in a few years to become a burden on the pay-rolls, and that the causes of exclusion included cases of marked tuberculosis, organic heart lesions, Bright's disease, deafness, irremediably poor sight, as well as tuberculous spinal conditions, still in the active stage, it will probably be admitted that the examination is not altogether without its usefulness.

But the point to which all of this leads is this: I have been repeatedly amazed at the low standard of health among the younger groups of candidates, those coming from our high schools, Normal College and College of the City of New York. The Normal College, as a rule, sends us between five and six hundred a year to examine, the Boys' City College a much smaller number, and the output from the high schools of Greater New York (entering the Training Schools for Teachers) averages over six hundred every six months. Few of these candidates are under eighteen; few over twenty-four. These form the bulk of our examinations.

In this younger group especially, are found many cases of anemia, albuminuria, and organic heart lesions. The cases of anemia and of functional heart trouble are as a rule readily cured. Given a rest from the strain of school and other work, and a few weeks or months in the country, and they usually pass the reexamination in the fall. But it is found that the cases of albuminuria have been strained a point farther in the matter of endurance and do not respond so easily to rest and treatment. Many applicants upon being notified of the cause of their temporary rejection put themselves under the care of their physicians; others were under the supervision of well-known specialists; yet the drain upon the system continued in spite of the best of treatment, often for many months and in some cases for years. Tests were made at frequent intervals to determine the improvement. Many of these cases came as a complete surprise to the examiner, the family and the family physician; it was the first note of warning. But the stubborn fact remained that these boys and girls had worked and worried a point beyond the limit of healthy reaction, and that an important organ was in a fair way to become permanently damaged. Some cases had passed beyond the limit of simple albuminuria and showed distinct evidence of permanently damaged kidneys. There were only a few, however, of these.

It had been the custom of the Board physicians to examine the Normal College girls and the College of the City of New York boys immediately after their written examinations. This meant that they came to us after the prolonged strain of their own faculty examinations plus those given by the Board of Education. It was a noticeable fact at that time that the number of cases showing this condition of the kidneys was very large, comparatively. The examiners then tried giving these applicants their physical before their academic examinations, with much better results, showing conclusively: (1) That a strain of even a few weeks may produce in these young people a temporary derangement. (2) That those with organisms sufficiently strong react immediately upon removal of the strain. (3) That a small percentage have had the way paved for permanent injury to a vital organ.

One expects the kidneys of a man of over fifty, subjected to the strain and worry of a hard business life, to show evidences of wear and tear, but one does not expect weakness in the kidneys of the young adult, at least, not in any such proportion of cases as the examinations have brought to light.

As to the frequency, comparatively speaking, of organic heart lesions, I confess myself fairly puzzled. The majority of these cases occur among the boys, especially those of foreign birth. These boys are often anemic, generally undersized; many show no other evidence of anything wrong. In many cases no amount of questioning has sufficed to bring to light an adequate cause for the valvular difficulty. Sometimes the diagnosis of organic trouble has been questioned by the family physician, but an appeal to the specialist or an attempt to obtain

a life insurance policy has proven the existence of the lesion, however inaccessible its origin. They can scarcely all be congenital. Is it not possible that the defect is nutritional, *i. e.* that it owes its origin to defective nutrition in infancy and early childhood? This is the conclusion to which I have been forced in the years in which I have watched these cases. Many of them are temporarily debarred until their general condition is improved, and often, while under reexamination they have voluntarily disclosed the hardships and privations of their early and oftentimes of their present lives.

It is the story of the immigrant family, of the ambitious father and mother, and of the no less ambitious son or daughter; of the educational facilities, so new to them, so within reach; of the struggle at home to make the scanty loaf go round; of the goal at the end—$900 a year to the successful lad, $600 to the successful girl—with all that it means in the way of an immediate uplift, better living, better food, and the chance for the younger brother or sister to be kept in the educational path. Is it not a goal to be striven for, even at the temporary sacrifice of much needed food, much needed sleep, much needed recreation? Many a time are the hearts of the examiners, generally accredited with being hard as flint, softened almost to the point of passing some ineligible who would in a short time become a burden upon the pay-roll.

It is right here that the connection between our work at one end of the line and the work of the Board of Health and that of the Board of Education at the other end, comes in. *We* get the finished product of the public school system: *they* deal with the raw material. Ours is a sifting process, a cutting off of the weakly, an applied survival of the fittest: they can preach prevention, prevention, and again prevention, all along the line.

The influence of these physical examinations is reaching down through the high schools and lower college classes gradually, and the pupils are beginning to recognize that ill health is a poor credential to present to the Board, backed up even by the family physician's certificate that the condition of the candidate is due to strain and overwork. Ambition that strains its possessor beyond the safety point physically defeats its own ends, no matter how high may be the mark received for academic attainment. If even this baldly utilitarian aspect of the value of a sound physique could be hammered into the boys and girls from beginning to end of their high school and college courses, we should find the names of fewer honor students on our list of rejections for physical disability. Still, as I said, the influence is percolating down and the percentage of rejections becoming smaller.

But the ounce of prevention must be administered still earlier to obtain the best results. Down in the crowded districts of our city are thousands of families, representing tens of thousands of school children. The majority of these are foreign born. The parents, accustomed to a certain diet in the land of their birth, got along—that is, they lived and grew up. But the conditions of living here are vastly different, and the children's needs cry out for more liberal nourishment. Many of the mentally and physically defective in our schools come from this class, and Dr. Elias Brown, examiner of defective children, has repeatedly pointed out, as, of course, have many others, the fact that nutritional defects are the basis of a large proportion of these cases. Not only are these children fed wrongly, but they often are not fed enough. Many and many a principal has told me of little ones in school without breakfast, whom they and the teachers have fed. And while the discussion goes merrily on as to whether the feeding of these little ones *in* the schools by the city would tend to pauperize the family, the children keep up a vain and weary struggle to satisfy their mental needs on an empty basis—that is, a hungry stomach. Is it any wonder that lean, stunted, dwarfed intelligences result? I know it is a large question, one with many sides, but the fact of malnutrition among the children of this group is so apparent, so easily demonstrable, and the pernicious results so long lasting, that it would seem time for at least a partial experiment to be tried, along the lines of ampler satisfaction for downright physical need.

The statistics given by Dr. Cronin of the Health Board at the meeting of the Society of Health Board Inspectors at the Hall of the Board of Education, November 16, 1906, were, to say the least, startling. The prevalence of adenoids, enlarged glands, chorea, catarrhs of eyes, ears, nose, throat amongst our school population showed most strongly the need of preventive work even further back than the time when the child enters the schoolroom. All of these troubles are preventable, many, if not all of them, dependent upon poor nutrition. Right into the homes must the ounce of prevention be carried. The ratio of its value to the pound of cure is none exaggerated.

Of course there are other sides to this question than the one of the duty of the city to its school children. Parents are many times to blame for the physical breakdown of the growing school girl or boy. Over and over again have I questioned the advisability of keeping boys and girls at high school or college whose parents could ill afford the expenditure entailed in the loss of money which would have been coming in had the boy or girl been at work. There are in our high schools and free colleges to-day sons and daughters of the very poor, the widowed seamstress, the washerwoman, striving to keep up a struggle lasting five, six and now in both colleges, seven years. We honor the self-sacrifice which toils and complains not, but if the struggle is being kept up on insufficient nourishment and with the probability of physical breakdown before the goal is reached, is it worth while? I often feel that many of these lives could be lived just as sweetly and far more healthily and serenely on different lines. But the social position of the teacher in New York, the permanency of the position once attained and the fairly high salaries, are great temptations, especially to our young women.

"Your daughter is ill, anemic, nervous, run down, not fit to teach in her present condition," and the reply always is, or very commonly, "She has not had sufficient food: it has been a struggle to keep her at college; there are others too, to feed, and I am the only wage-earner. The salary of her first year will put us above want. It will give us all the food we need," and then, too often, comes the personal appeal, so hard to resist, to give her a trial "for charity's sake." One little girl, an upstate candidate, came to us, well advanced in pulmonary tuberculosis. We did not tell her the cause of her rejection the first time, feeling that if her family physician had not seen fit to do so it was not our business, and within a year, at considerable expense for railroad fare, she reported again. It was the same story—a self-sacrificing, ambitious mother and a family who had "gone without" to "get her through." There was no shadow of a chance for her.

One lad, whom a very marked organic heart trouble, coupled with failing kidneys, debarred, told

me that his parents' sole support depended upon him; that they had striven painfully to the limit to have him finish his course and now were too old to work longer. Another had gone through on money borrowed from a friend, to be returned from his first salary.

But, as I stated before, I believe our work is becoming, in a measure, preventive. Knowing that this examination looms ahead, the girls are themselves more careful and their parents have been awakened. Many a girl is now sent, well or ill, to the family physician for a general overhauling some time in advance of our examination. Students with spinal trouble, extreme nearsightedness, organic defect, or deformity often ask advice in their early college years as to whether it is worth while to continue with the distinct idea of becoming a public school teacher. Others, positively defective, drop out by the way. But the more insidious forms of trouble continue to be overlooked, to the great disappointment of the candidate when refused on the physical examination.

Possibly many will find in my statements food for criticism on the amount of work required of our high school boys and girls. No such criticism is intended. Far more is it my purpose to call the attention of parents and physicians to a better care of the growing boys and girls under their charge, as to diet, hygienic surroundings, healthful exercise; to an insistence on more sleep and less excitement. The unexpected results of these examinations, and they number between four and five thousand cases (plus those referred to me by the other examiner), added to a large personal experience with school girls as physician and one-time teacher, have proven, to my own satisfaction at least, that the foundation of many a long-lasting, if not incurable, condition is laid during school life. The average high school girl could accomplish her work with far more credit to herself and less detriment to her health if her life outside of school hours were planned with more forethought and a deeper insight into the dangers which beset the growing girl in the way of outside distractions. Several matinees or theater parties a week, a large amount of miscellaneous novel reading, late hours, injudicious food, an unbelievable amount of coffee —add these to the normal strain of school or college life, where the work of each day must be closely welded to that of the day before and the day after, and where the least break means trouble and disaster, and you have paved the way for these very conditions of which I speak, conditions due to strain, which should be wholly unknown in the life history of the young adult.

1 West One Hundred and First Street.

THE SOLUTION OF THE LODGE AND SOCIETY PROBLEM OF THE EAST SIDE.*

By JULIUS WEISS, B.S., M.D.,

NEW YORK.

The practice of medicine on the East Side in New York is unique. It differs from the practice of any other section of this country for the reason that in this locality almost 75 per cent. of the population are insured for medical attendance in lodges and societies. Here also three-fourths of the physicians accept contract practice from these organizations. While many of the conditions described below may apparently deserve censure for the physicians, still, upon careful reflection, it will be seen that in reality no physician can be blamed at the present time. The conditions described herein were forced upon a badly disorganized body of 300 conscientious and industrious physicians by a strongly organized body of men, numbering thousands, and working through the medium of well-established lodges and societies. No excuse, however, should in the future be accepted from any physician of the East Side, who, after reading this article, should still refuse to join with his colleagues in promoting the necessary reforms.

It is the purpose of this article to point out the rôle the physician is forced to play in these lodges and societies, the conditions he is confronted with therein, and to suggest a plan for the amelioration of some of the existing evils.

The young graduate who hangs out his shingle on the East Side usually starts with such financial resources that he cannot afford to wait until he establishes a private practice. He must from the very beginning seek other means whereby he may be able to pay his immediate expenses. He very early learns that there are in this section hundreds of lodges and sick-benevolent societies employing physicians on contract practice, each of which insures an income for the physician of from twenty-five to one hundred dollars quarterly. It is therefore natural that a young physician should under the circumstances make an effort to obtain such employment.

The question, "How long shall a physician of the East Side accept society practice?" is still a debatable one. The facts are that of the physicians who had society practice and dropped it, some have succeeded in establishing a paying private practice, while others have failed. Time alone cannot be taken as a criterion for the retaining or dropping of societies. Physicians should be permitted to retain societies until they feel that they are sufficiently well established and can earn a living from private practice alone. This should be a matter for personal decision.

At the present time many physicians of the East Side who are from eight to fifteen years in practice find that it is still advisable for them to accept society practice. This being the case, it happens very often at elections that old physicians find themselves competing against one another, as well as against younger men. As they are all anxious to be elected, usually each in turn will make some concession to the lodge or society to gain votes. Oftentimes candidates for an election go even further than merely making concessions. Some of them, in their anxiety to be elected, make preelection banquets for the more influential members. Others go a step further —they offer bribes to gain votes.

The results of this condition of affairs are that the physicians become disrespected, the tone of the profession is lowered, the remuneration for medical services becomes ridiculously small, physicians are compelled to accept impossible conditions, and they are forced to care for a large number of families, whom they cannot properly attend and whom they can almost never carefully examine when called. Finally, promising physicians with high ideals lose their interest in medicine as a science, disregard their colleagues, and themselves become disregarded by the laity.

I have stated above the true conditions of the medical profession on the East Side because I share the opinion of many others, both physicians and laymen, that it is high time for medical men to unite and by concerted action to introduce certain neces-

*Read before the Physicians' League, Friday, January 24, 1908.

sary and important reforms. And unless the matter is brought clearly before them and full publicity given, nothing will be done.

What shall these reforms be? The suggestions made by physicians are numerous and varied. The more or less independent physicians would like to have society practice abolished entirely. Others argue that all we have to do is to agree to increase the present rates and improve otherwise the conditions of the contract. Some physicians suggest that the dispensary evils be first ameliorated; others, again, that pharmacists should be punished for counter prescribing, and finally a number of practitioners are skeptical as to the possibility of instituting any kind of reforms.

I am convinced that society and lodge practice on the East Side will continue for some time to come. There will always be some physicians compelled to take society practice, especially in the first few years of their profession, as it insures for them a steady income. It is therefore out of the question, for the present at least, to abolish this kind of practice. It plainly cannot be done.

Many physicians are agreed that the terms of the contract should be greatly modified and improved. At present a physician gets from one to three dollars per annum to treat an entire family when sick. He may be called at almost any hour of the day or night. He must treat all except immoral ailments without any extra cost to the patient. He must accept patients no matter in what part of Greater New York they may happen to reside.

The three hundred physicians of the East Side taking this kind of practice ought to be able to agree upon a uniform contract with improved conditions as to rates to be charged, hours of attendance, distance to be traveled, and the nature of the work to be done.

At this point we ought to consider the opinions of those skeptical men who do not believe in the possibility of such an agreement among the physicians of the East Side. To a certain extent these pessimists are correct. They know that in the past a number of attempts at organization for such reforms were made and that they were all failures. It may be predicted with safety that future attempts of such a nature will also be failures, unless one all-important fundamental reform in contract practice is first instituted, namely, the abolition of the custom of electing physicians in organizations, and the substitution of a system that will eliminate this form of competition. A system of selection, which will be discussed below, must be established, so as to give each and every physician interested a fair chance to accept contract practice, and which will place him in the same relation to the contract patients as he is to his private patients.

While the right kind of competition among medical men is healthy, that is, competition in which one physician endeavors to rival his colleague in knowledge, skill, and conscientious effort; on the other hand, the form of competition which is directed towards lowering of prices, of professional dignity, and of medical efficiency, is detrimental to the moral, economic, and professional welfare of the physician. This sort of competition has already proven a complete failure from every point of view.

By the system of election a physician knows that if he gets one vote less than his competitor he will be defeated entirely, while the successful candidate will get on his list not only those who voted for him, but also those members who voted against him and who preferred the defeated candidate. By this system of election a double injustice is done. The unsuccessful physician is robbed of the income from those who voted for him, and his friends are deprived of the medical services of the man whom they personally desired. The physicians, therefore, recognizing the great importance of having a majority of votes, will use all means, fair and unfair, to gain an election. But by eliminating this element of chance and by giving each physician an opportunity to obtain a list of as many members as prefer him, we shall create favorable conditions for instituting the necessary reforms.

Under the system of selection a physician will first be asked, as it is done to-day, whether or not he is willing to accept a list of members from a certain lodge or society. If he consents his name will be presented to that organization for selection. Each member of the organization will then designate on a uniform prescribed card the name of the physician by whom he wishes to be attended. The members could fill out these cards at their homes, after which they could mail them or bring them to the secretary of their organization.

After the cards are in the hands of the secretary one of three things may be done.

1. The cards may be assorted by the secretary of the lodge or society and each physician is then given a list of the members who subscribed for his services.

2. The selected physicians of a lodge or society may meet and elect one of their group as foreman. The cards are then assorted and each physician receives his list as in the first instance. At the end of the quarter the foreman collects the amount due for medical services and each physician receives his proportionate share.

3. The cards of an organization may be sent to an office established by the physicians for that purpose.

The organization in question is then debited with the correct amount for medical services based on uniform rates.

The cards are then assorted as are letters in a postoffice, each physician's cards being put separately. Each physician is then credited with the total amount due him as is represented by the total amount of cards sent in from the various organizations.

At the beginning or end of each quarter of the year this physician's office collects all moneys due from the different societies. A check is then sent to each physician for the amount he has been credited with.

This system is comparable to the modern banking system, where the Clearing House bears the same relation to the bankers as the physicians' office would to the physicians, except that in the case of the physician the system is greatly simplified.

Of the three systems, the third just described is very likely the best. It does away with the physicians having to act as collectors in each of the societies where they have been selected, or with having to meet to elect a foreman to act for them. It saves them much time and disagreeableness. It does not give the societies a chance to deduct from the physicians' pay for treats and banquets. By this system also the physicians will be regarded by the various organizations from the professional standpoint only and all ideas of commercialism will be removed from the minds of the laity. By this system, also, no physician has to worry about

defeating or being defeated by any one, as each one will get a list of as many members as sympathize with him. He will then readily see that it is to his advantage to cooperate with his colleagues for the purpose of maintaining a uniform contract and a proper professional dignity.

Before concluding this paper one more proposition has to be discussed. What arrangements shall be made for the physical examination of candidates for lodges and societies? If the system of election is to be abolished, who will act as the official examiners of these organizations?

One easy way of disposing of this question is by adopting a method already in vogue in some organizations. In certain lodges and societies where there are more than one or two physicians as members, each physician takes his turn as examiner, serving a proportionate length of time. But it appeals to me that there is a better and more just way of disposing of this question.

In the first place it is clear that the success of maintaining a uniform contract will depend upon enlisting the cooperation of the greater majority of physicians accepting society practice. Secondly, that such cooperation can be hoped for only when you establish the system of selection, thus eliminating the element of chance and giving each physician concerned a fair chance to obtain this kind of practice. But even under these circumstances there will be some physicians who will fall below par. This will especially be true of those physicians who are in their first and second year's practice. These may not get a sufficient number of sympathizers to subscribe to them to insure an income commensurate with their immediate needs. Under such circumstances it may be expected that such physicians will fail to cooperate for introducing the necessary reforms.

I propose to suggest here a very simple system whereby the young physician and even the unsuccessful older practitioner shall attend to the examinations of candidates, thus insuring them a definite income until they become better acquainted and have increased their practice. These physicians being insured by such an income will find it also to their advantage to cooperate for the maintenance of a uniform contract and a proper professional dignity.

The total amount of fees paid annually by candidates to all the physicians of the East Side amounts to about fifteen to sixteen thousand dollars, or an average of about fifty dollars for each of the three hundred physicians. I propose to suggest that this money shall be earned by only thirty or forty of the younger and less successful practitioners. This would give each an assured annual income of about four hundred dollars, in addition to the income from society and private practice.

The new method of examining candidates could very easily be worked as follows:

Two or three offices could be established in different parts of the city where candidates shall be examined. The younger and less successful practitioners could be assigned in routine to examine candidates. The applicants for membership could be notified by the secretaries that they must call at one of these offices for a physical examination. Certificates of admission could be issued by these physicians on uniform blanks. An established fee could be paid by these candidates to a cashier in each office, and quarterly these moneys from the various offices could be equally divided among these examining physicians.

By this system of physical examination the lodges and societies would be strongly protected against the admission of sickly members, as the examinations would be conducted by entirely disinterested men. The physicians also would be protected. For, by throwing such an income in the way of these physicians, their goodwill would be secured as well as their cooperation towards the maintenance of a uniform contract and a higher professional standard.

Summary.—1. The practice of medicine on the East Side is unique. Seventy-five per cent. is lodge and society practice. Three-fourths of the physicians on the East Side accept this kind of practice.

2. The laity is organized, the physicians are disorganized.

3. To gain contracts, physicians have to go through elections.

4. To insure being elected, physicians make the worst concessions and lower their professional dignity.

5. It is necessary for the physicians to cooperate to establish a uniform contract, and to raise the professional standard on the East Side.

6. To accomplish these reforms it is necessary to abolish the "system of election" and to establish the "system of selection."

7. To gain the good will and cooperation of the new and less successful practitioners, it is necessary that the older and more successful practitioners allow the former to examine candidates of the various lodges and societies.

8. There shall be established offices where the examining physicians shall be assigned in routine for the examination of candidates. The income from these candidates shall be divided in equal shares quarterly among the examining physicians.

A CASE OF CUT THROAT.

By CHARLES I. PAGE, M.D.,

LITCHFIELD, CONN.

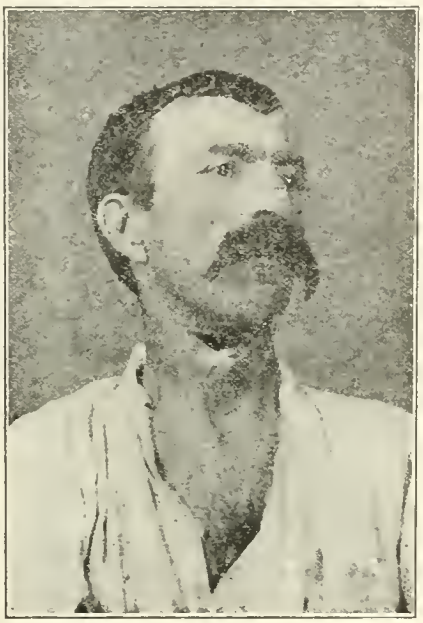
As extensive wounds of the throat, made with suicidal intent, are in the majority of instances fatal, either from the primary hemorrhage or from complications, it has occurred to me that the following case might be of sufficient interest to report.

J. E. T., age 35 years, a prisoner in the County Jail, charged with burglary and arson. On July 24, 1906, he attempted suicide by cutting his throat with a potato knife. The man was found about half an hour after the act had been committed, lying in his cell unconscious. On examination, we found a wound extending from one sternocleido muscle to the other; both carotid arteries were exposed, but had escaped injury. By inserting the first and second fingers in the wound, I could easily introduce the first finger between the vocal cords into the trachea, while the second finger passed into the esophagus. The knife struck the thyroid cartilage about one-eighth of an inch below its upper margin, slipped upward, and entered the tissues above the thyroid, severing both superior cornua of this organ.

Hemorrhage, which had been very profuse, was checked. Enema of a quart of salt solution was given, and also a hypodermic injection of strychnine. The head was lowered. The thyroid cartilage was sutured to the upper side of the wound by three catgut ligatures. This operation was difficult, as the trachea moved up and down with each respiration. The skin wound was closed with

catgut. On the following day the dressing was removed, and we found that some of the superficial, and all of the deep sutures had torn out. From this time on the wound was dressed twice daily. Nourishment was given per rectum for three days. As the man was now conscious, he was fed through the stomach tube until the tenth day, when he was able to swallow fluids.

The photograph from which the illustration was made was taken on the sixteenth day, and shows the wound had healed by granulation for about half an inch on each side. The man was now able to swallow fluid nourishment, providing the wound was covered with a dressing, but if there



From a photograph taken on the sixteenth day.

was no dressing the fluids would gush out through the wound. He did not suffer any pain. The principal inconvenience was spasms of coughing, especially when taking food.

At the end of six weeks the wound was completely closed, and the man was now able to eat the regular prison rations. At the end of the third week he could converse in a whisper; the voice rapidly improved, and at the end of the eighth week he was able to talk in the ordinary tone of voice. The man on seeing one of these pictures asked if he might have one to send to his wife, as he had not been photographed in twenty years. His request was granted.

Cryoscopy in the Diagnosis of Renal Conditions.—A correspondent calls attention to the fact that nearly every clinic in Budapest makes use of this method. This, he says, is not surprising, because the phenomena connected with the depression of the freezing point were first made known in Budapest in the clinic of Professor Korànyi, who is still busy with the study of cryoscopy. An expert clinician has, however, lately expressed some doubt as to the trustworthiness of this method. He said that the character of the food and the amount of fluid ingested seem to have a marked influence upon the freezing point of the urine, but even if the diet is simple and absolutely uniform the figures vary within very wide limits. Several cases have been reported in which the wrong kidney would have been extirpated if nothing but the "molecular concentration" of the urine had been taken into consideration. Much more satisfactory results are obtained if attention is also paid to the daily amount of urine and if renal activity is expressed in so many daily molecules. In all cases the diet should be controlled and the catheters should be introduced at a definite period after a meal and left in position for at least two or three hours, since fluctuations are very common. At best the method is only approximate, but though troublesome it offers valuable aid in conjunction with other data.—*The Lancet.*

Acute Gangrenous Pancreatitis.—D. J. Jones reports one case, with a successful result following operation. His patient was a woman of forty-four years with a three months' history of vomiting followed by epigastric pain and general abdominal soreness. Jaundice was wanting. Three days before admission to hospital she ate some cucumbers at night. Vomiting came on next morning and continued. Examination showed the abdomen full and rigid in upper right quadrant. A distinct tender mass could be felt in the region of the gall-bladder extending downward nearly to the navel, and she was slightly jaundiced. Abdominal exploration was deemed advisable and an incision was made through the right rectus from the costal border downward. Gall-bladder and stomach were normal. The bile ducts could not be thoroughly explored because of the mass. Just below the border of the liver was a mass adherent to the anterior abdominal wall and extending posteriorly to behind the stomach. This mass was made up of gray necrotic fat tissue into which the finger could be pushed with ease. It extended to the region of the pancreas and across the spine over the pancreas. The whole mass was broken up with the finger and packed with several strips of gauze with a tube in the center. The condition of the patient was so bad that posterior drainage was not attempted. The convalescence was long and tedious, but the patient was immediately relieved of pain except at intervals when she would have considerable pain with an increase of temperature. The temperature during the greater part of the time was between 99° and 100°. She left the hospital in eight weeks with a small sinus which closed in a short time, since when she has been perfectly well.—*Boston Medical and Surgical Journal.*

High Frequency Currents in Excessive Arterial Pressure.—A correspondent, whose name is not given, writes an interesting letter from Paris referring to the work of Montier along the line indicated in the title. The latter does not claim to cure arteriosclerosis as a lesion, but claims to be able to reduce excess of pressure with perfect ease, and that this reduction is to a certain degree a definite one. His apparatus is thus described: a Ruhmkorff coil giving a 25 cm. spark, fitted wtih a Contremoulins-Gaiffe interrupter, connected with the city cables by a rheostat; a d'Arsonval petroleum condenser, and a large solenoid cage with continuous wire and no door, the hoops being hoisted up to let the patient in. The treatment is supposed to be given at about 500,000 interruptions per second. By means of high-frequency currents of high tension applied in a solenoid cage in sittings of five minutes each, given three times a week, he claims to reduce high pressure and thereby to ameliorate many symptoms—such as vertigo, palpitation, irregularity, etc., connected with developing arteriosclerosis and to retard its development by removal of pressure. The existence of tuberculosis contraindicates this method of treatment. The correspondent adds that Montier's claims are not accepted by his medical colleagues or by electrical experts in medicine. The method is based on the theory that the arteriosclerosis is preceded and produced by a long antecedent period of high pressure due to capillary spasm. This is denied by the Paris physicians and the most they will admit is that the reduction of pressure by Montier's method is but temporary and evanescent.—*Boston Medical and Surgical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 11, 1908.

A NEW RADIOTHERAPEUTIC METHOD.

VARIOUS radiometers and other devices have been conceived to control the dosage of *x*-rays and thus to diminish the resulting danger from exposure to them. These instruments may be of value when the question is one of treatment of skin affections, but they are quite useless when the internal organs are to be subjected to the action of the rays. Successful treatment of the latter requires frequent and prolonged exposures so that we are always facing the possibility of an *x*-ray dermatitis, if not something worse. A method of reaching the internal organs without the possibility of a dermatitis setting in would therefore seem desirable. With this in view R. von Jaksch (*Zeitschrift für klinische Medizin*, Volume 64, Nos. 3 and 4) carried out a series of experiments. He found that a lead plate four-tenths of a millimeter thick did not transmit the *x*-rays after exposure from one to nine seconds. When such a plate was placed between the rays and the body the skin remained unchanged after frequent exposures of fifteen minutes; blood changes were also absent, thus proving that a lead plate four-tenths of a millimeter thick prevented the *x*-ray from reaching the skin or deeper organs. A lead plate two-hundredths of a millimeter thick, on the other hand, transmitted the rays and did not prevent a dermatitis after several exposures of fifteen minutes each. A silver plate two-hundredths of a millimeter thick transmitted the rays more readily than a lead plate of the same thickness, as was seen on a photographic plate, the shadow being more distinct after two seconds' exposure with a silver plate intervening, than after three seconds exposure with an intervening lead plate. It would therefore be natural to suppose that a dermatitis would be more readily caused after long or frequent exposures with an intervening silver plate than with an intervening lead plate. The experiments of v. Jaksch, however, showed that the skin was not affected when the silver plate was used, although the characteristic blood changes due to *x*-rays were found. The silver plate thus permitted rays to go through it which affected the deeper organs while it prevented the transmission of the rays which affect the skin.

Von Jaksch found this to be the case in many patients and cites the history of one with splenomyelogenous leukemia, treated by the *x*-ray with an intervening silver plate two-hundredths of a millimeter thick. The patient's general condition improved, the spleen became very much smaller, the percentage of the pathological leucocytes came down to normal, that of the polynuclear neutrophiles rose to normal, and the total number of white blood cells was reduced from 252,000 to 5,000 in six weeks. Twelve different portions of the body were exposed to the *x*-ray with an intervening silver plate, from three to five times, each exposure lasting from fifteen to twenty-five minutes, so that each area received *x*-ray treatment for from one to two hours. The patient did not develop a dermatitis. Von Jaksch does not claim that the *x*-rays permanently cure leukemia, but does claim that his observations positively show that the internal organs can be effectually reached with the *x*-ray, without injuring the patient, when a silver plate of the above mentioned thickness is placed on the skin. The tube is placed twenty centimeters from the body and the part of the latter not covered by the silver plate is covered with lead.

Von Jaksch has proved that a lead sheet two-hundredths of a millimeter thick permits rays affecting the skin to pass through it while a silver plate of the same thickness does not transmit such rays. The silver plate, however, transmits a greater number of rays than the lead plate, for the shadows on a photographic plate were more distinct with an intervening silver than with an intervening lead plate, after the same length of exposure. From a study of von Jaksch's observations it would seem plausible to suppose that the *x*-rays are not all of the same kind and that certain metals will permit only certain rays to pass through them, and that sooner or later we may find a specific radiotherapy for the various organs.

VASOMOTOR COLLAPSE IN ACUTE INFECTIONS.

IT is well known that many truths concerning the behavior of the animal organism in health and in disease after being experimentally established, only slowly filter their way into the general books on medicine or gain currency in actual practice. In general this is salutary, for it checks the rash application of the results obtained in experimental research before they have been verified by other workers under different circumstances of observation. Occasionally, however, many physicians continue to cling to old ideas in theory and in practice in the face of well established experimental and clinical data. Writing in *Russkii Vratch* (Nos. 4 and 5, Vol. VII), Dr. E. B. Blumenau cites one instance of this, the popular view, namely, as to the cause of early collapse in many acute infections. "Heart failure," "acute dilatation," "myocardial insufficiency," etc., are the expressions often loosely used to explain this serious phenomenon, yet careful laboratory work has abundantly proved that the primary cause of this condition is to be sought not in the inefficiency of the heart but in the state of the vasomotor system of the body. Romberg and Pässler (*Deutsches Archiv für klinische Medizin*, Vol. 64, 1907) have shown that asystole or incomplete systole of the heart accompanying early collapse in acute infections is due primarily to a dilatation of the blood-vessels in the body, especially those of the great splanchnic system, thus interfering with the usual supply of blood to the heart and taking away

an important element in the mechanism of its contractions.

Accordingly, all medication that may further diminish the general blood pressure is distinctly contraindicated, yet even such a frank vasodilator as nitroglycerin is often given. Nor is the use of pure heart stimulants much more called for; the heart muscle is usually willing and able to do its work, and whipping it up without bringing to it the necessary conditions for its activity is, to say the least, a useless procedure. The real state of affairs is very much analogous to shock in surgical conditions, and Crile has clearly shown the futility of stimulating the heart alone in such circumstances. Of course, the most rational therapy would be the use of specific remedies, destroying the infective organisms or binding the toxins produced by them before the vasomotor system has been overwhelmed. However, neither the pharmacological nor the bacteriological laboratories have as yet given us specifics for such diseases as typhoid fever, pneumonia, scarlet fever, etc., and one must have recourse to drugs that fulfil at least one important indication, namely support and stimulation of the vasomotor system as well as the heart. In Dr. Blumenau's experience with pneumonia digitalis and camphor have proved to be most reliable, the former as a general stimulant to the circulation, the latter especially in the grave conditions of collapse characterized by vasodilatation and rapid fall of blood pressure. On such occasions the author has often made use of subcutaneous injections of camphor dissolved in oil, the administration being repeated as often as every one or two hours and the dosage above the usual averages for this drug. In no case were any untoward results noted, while on many occasions such medication appeared to have tided the patients over the most critical periods of their disease.

There is, of course, little that is new in the above considerations, yet the article of Dr. Blumenau is worthy of notice for laying stress upon the correct conception of collapse in such acute infections as pneumonia, and for his insistence upon the necessity of shaping treatment in accordance with such conception.

PRISON MANAGEMENT.

Those whose years and memories are long enough to enable them to compare the lot of the prisoner of to-day with that of the delinquent of a third of a century ago are tempted to believe that humanity has gone as far as it legitimately can in the treatment of the criminal whom the law has separated from his fellows for the latter's good or for his own. Any further lightening of the just punishment of the law-breaker seems to them to border on the dangerous, to tend to make prison life too easy, and to remove from it its punitive character. We have no sympathy with the sentimentalist who would make of a term of imprisonment in the county jail a pleasant vacation and a time for sobering up in a comfortable home with good food and abundant leisure preparatory to a fresh bout on the Bowery or in the Tenderloin. There is room, also, for considerable skepticism regarding the reforming influences of imprisonment under any conditions, good or bad; but at least the punishment should not be inflicted in such a way as to confirm the criminal in his evil courses or to turn the accidental law-breaker into a hardened sinner. Yet such, say those who know best, is the usual result of a term of imprisonment under the present conditions. The management of the prisons is left too much to wardens and keepers who may or may not be morally much superior to their charges. The regulations read well, but they are fatally defective, in practice at least, in that there is no effective provision for ensuring their faithful observance. There is too little supervision by persons whose political or personal interests do not lead them to wink at certain things of which the conscience may not approve, and too much authority is given to officials whose observation of only one side of the criminal, and that the worst, tempts them to undue severity if not actual brutality in their treatment of the helpless and unlovable creatures temporarily in their power.

In a letter in *Charities and The Commons* of March 14, Dr. Beverley Robinson directs attention to some of the present day abuses in our prisons and suggests certain remedies for them. He says that the prisoner should work hard and should be subject to strict regulations as regards conduct and obedience to rules, but at the same time there should be due consideration for his personal welfare. No reformation of the criminal is possible, Dr. Robinson holds, when he receives insufficient and bad food, and when light, air, and even warmth are denied him. In looking for a remedy of the evils of prison management, he says penal institutions should be governed somewhat as our charitable institutions are governed. The food should be daily inspected as to quality and preparation by competent persons independent of the prison authorities, and there should also be a consulting medical board on whom would devolve oversight and control, under the authority of the Prison Commission, of all sanitary and moral relations having to do with reform of criminals from the highest medical and ethical standpoint. It may seem a little strange, at first thought, to commit to medical men the task of the moral reform of those unfortunates, but there can be no uplift of the soul if the body is maltreated. There is much truth in the saying that the way to a man's heart is through his stomach, and not his stomach only, but his whole physical being. Of little avail are moral precepts to an underfed, air-hungry and soapless man. He must be fed and washed, his lungs must be filled with pure air, and the discipline to which he is subjected must be administered with justice, at least, if not with mercy. If there is a possibility of reformation it is only in this way that it can be effected. Brutality on the part of the keepers will only make the prisoner himself more brutal and confirm him in his enmity against society.

SOWING THE SEED OF ALTRUISM.

A few years ago a lady of this city, impressed with the unnecessariness of much of the noise which pounds the ears and racks the souls of urban dwellers, set herself the task of suppressing it so far

as might be. She first attacked the captains of tugs plying on the rivers who were in the habit of calling their crews from the saloons where they spent their leisure moments by shrill blasts of whistle and siren. The personal motive which may not improbably have first suggested her action, was soon lost in a consideration of the distress such noises caused to the sick in the hospitals and in the homes along the river fronts, and then of that caused by the ordinary street noises to the inmates of hospitals wherever situated. This consideration has led to the inception of a movement the results of which, both direct and indirect, must be of a far-reaching good to the community that is well-nigh incalculable. Encouraged by the measure of success which her own unaided efforts had secured, Mrs. Rice invited the cooperation of others and established the Society for the Suppression of Unnecessary Noise. The defense of the sick in the hospitals from sleep-destroying noise was the special concern of this society, and the thought was conceived of safeguarding these sufferers by establishing areas within which special effort should be made to secure an abatement of the ordinary street noises. With the active and moral support of the members of the society, yet largely through her own effort, Mrs. Rice secured the passage by the Board of Aldermen of an ordinance establishing quiet zones in the immediate neighborhood of the hospitals of the city, and signs have been placed at the street corners limiting these zones, warning drivers and other users of the streets to reduce the speed of their vehicles and in other ways to observe the rule of quiet.

Attention having thereby been specially directed to the sources of unnecessary noise in hospital neighborhoods, it was found that the vicinity of a hospital was particularly enticing to those large numbers of children whose playground, for obvious reasons, must ever be the street. The going and coming of ambulances provides for these children that special spice of life—the titillation of horror—which their elders and betters procure for themselves in other ways, according to their standards. A child engaged in open-air play is a noise-producing animal, and properly so, but the least sensitive imagination may wince at the thought of what these child-haunted hospital sidewalks must mean to hundreds and thousands of helpless invalids. It was wisely thought that the only reformation possible for this state of things was to encourage the reforming spirit in the children themselves, and a children's society was formed to that end, called "The Children's Hospital Branch." The beginnings of this branch have been most interestingly detailed by Mrs. Rice in an article in the current issue of the *Forum*. There are to be no warning notice boards, no patrolling policemen, no prohibitions, adding the lure of the forbidden to an already existing temptation. Instead, these children of the streets are invited to become little brothers and sisters of pity, and pledge themselves of their own accord to help to guard the sacred silences that should hedge the very sick. More than twenty thousand children have already been addressed by the founder of the Children's Branch on this subject, all of whom are eager to be enrolled as members. They are asked to promise "not to play within a block of a hospital, nor in front of a house where some one is known to be very sick," and each child is presented with a badge to wear as a reminder of the promise. Each child is also given a blank membership card on which it is asked to write in its own words just how much it is willing to do for the patients in the hospitals. The naive and touching wording of many of these queerly-spelt promises would seem to prove that the sense of altruism is but lightly dormant in the smallest child, and it would be difficult to speak too highly of the wisdom that has known how to awaken it and start this much-needed reform.

Pepsin Secretion in Infants.

Of recent years the investigation of the digestive processes in infants has been pursued with considerable activity, and it has been shown that many of the preconceived ideas in regard to this function during the early weeks and months of life were inexact or entirely erroneous. This is true of the capacity of infants to digest starches, which has now been shown to exist in most cases at a very early period. Researches on the peptic activity of the infantile stomach have been less numerous and have also been unsatisfactory in that for the most part the determinations have been merely qualitative and not quantitative. Rosenstern (*Berliner klinische Wochenschrift*, March 16, 1908) has taken up the problem from the latter standpoint, using the method of Jacobi in which ricin is employed as the indicator for the pepsin content of the gastric juice. After trials of several forms of test meal he came to the conclusion that 50 c.c. of tea sweetened with saccharin was the most desirable, and extracted the stomach contents ten minutes after the child had begun to take the fluid. It was found that in healthy artificially fed children the pepsin did not appear in appreciable quantities until about the middle of the second month, but then increased until the end of the first three months, after which it remained fairly constant till the close of the first year. Healthy breast-fed infants produce less pepsin than those artificially nourished, and children that are under weight secrete the amount of pepsin that corresponds to their age. Observations on infants with digestive disorders showed that these did not appear to influence the pepsin secretion to any noteworthy degree, though in two cases of marasmus there was a diminution in the amount of ferment produced. These results invite further investigation of the question, and if confirmed, should prove of much interest to the pediatrists, as they may be interpreted as further evidence of the digestive power of the immature stomach to develop in accordance with the composition of the food that is put into it.

Angioneurotic Pseudoperiostitis.

The statements of patients that at times circumscribed tumors appear in different regions of the body to disappear again spontaneously, the symptom usually being associated in the sufferer's mind with some evidently wholly irrelevant condition, are ordinarily received by the physician with a certain amount of judicious skepticism. While this mental attitude is probably in most cases well justified, it must not be forgotten that the manifesta-

tions of angioneurotic edema may present themselves in some such way. While it is ordinarily the superficial structures that are involved in these swellings, Herz (*Zentrallblatt für innere Medizin*, March 21, 1908) describes a form having its seat in the periosteum to which he gives the name of angioneurotic pseudoperiostitis. The affection occurs in persons suffering from other forms of nervous instability, chiefly of cardiac nature, and the lesions always appear about the bones of the thorax. They consist of doughy swellings in the immediate neighborhood of a bone, and are tender and painful, while at the same time there is an exacerbation of the heart symptoms. The affection is readily amenable to treatment, warm applications being most effective. Owing to its nature it is readily mistaken for something else, and the author describes four cases, in one of which a surgeon seeing the tumor wished to operate for a supposed tuberculosis of the rib; in another it was proposed to inject gelatin into what was taken for an aneurysm of the aorta, while the pain in the other two was regarded as due to angina pectoris. While the condition is no doubt rare, a familiarity with its nature is desirable in order to avoid such diagnostic errors.

Roentgen Treatment in Dysmenorrhea.

Many forms of treatment are in vogue for dysmenorrhea, ranging from the conservative general treatment to the removal of the anatomically unchanged ovaries. In the *Centralblatt für Gynäkologie*, No. 5, 1908, M. Fraenkel reports twenty-eight cases of dysmenorrhea which were treated successfully with the *x*-rays. The painful periods disappeared after from ten to twelve exposures, and often after five. After they had disappeared once, treatment was suspended. The beneficial effects of the *x*-rays were, however, not permanent, for after three periods without pain the symptoms returned, and treatment had to be begun again, though now a few exposures sufficed again to relieve the patient. He considers the first week after the last day of menstruation as the best time for the treatment, and believes the good results are due to changes in the ovaries caused by the *x*-rays. Even if everything Fraenkel claims were true, it is probable that this form of treatment, if too long continued, would finally make the patient sterile, it is therefore undesirable in married women who wish to become pregnant. It is uncertain whether the sterility so produced is permanent. If it is permanent the *x*-ray treatment must be regarded simply as a rival of castration, but it would seem to be worth trying before the latter is resorted to, because by the *x*-ray the artificial menopause would be brought about more gradually than by double öophorectomy.

News of the Week.

Cuba Free from Yellow Fever.—Governor Magoon of Cuba has notified the Bureau of Insular Affairs of the War Department at Washington that according to the reports of twenty-six military surgeons stationed all over the island there is not a case of yellow fever in Cuba and that there is no need of a quarantine against Cuba. The Public Health and Marine-Hospital Service has nevertheless issued an order establishing a quarantine against Cuba with the exception of the metropolitan district of Havana, which includes Havana, Marianao, and Camp Columbia. This action makes Havana a "clean city" so far as yellow fever is concerned, but all of Cuba outside of that district is quarantined against. Major Kean, adviser to the Sanitary Department of Cuba, writes that the despatch from Mexico, published on March 14, to the effect that the ports of that country had declared a thirteen days quarantine against Cuba was incorrect; no quarantine of any duration had been declared by Mexico against Cuban ports.

Change in the Chicago Health Department.—Health Commissioner Reynolds of Chicago has divided the city into six districts. Each district is in charge of a medical inspector, who is to devote his entire time to this work, for which he receives $2,000 per annum. From now on, all employees of the Health Department will wear a uniform. Those below the grade of medical inspector will wear a blue blouse, with a single row of distinctive brass buttons, and a black soft felt hat. The medical inspectors will wear a double-breasted coat, with velvet collar and brass buttons, with a single gold star on the collar, and a black soft felt hat. The ambulance surgeons will wear a red cross on the left sleeve. The heads of departments will wear the same uniform as the medical inspectors, with two stars on the collar, and the commissioner will have three stars and a white soft felt hat.

Low Death Rate in New York.—During the months of January, February, and March the city's death rate was remarkably low. The Health Department's figures give the total number of deaths as 20,309, equivalent to a rate of 18.43 a thousand. During the past ten years the rate for this quarter has averaged 20.52 a thousand. The birth rate was also unusual, as the number of children born during the quarter was 32,655 as against 29,294 for last year, the ten year average being exceeded by 9,000. The number of marriages was 9,557, while last year there were 11,570.

Protection to the Oyster Consumer.—Health Commissioner Darlington of this city has published the following addition to the Sanitary Code: "Section 185.—No oysters shall be held, kept, or offered for sale anywhere in the City of New York without a permit in writing from the Board of Health and subject to the rules and regulations of the said board." Since most of the beds where oysters are fattened in sewage-polluted water are outside the city limits, the Health Department cannot control the practice directly, but by means of this new section of the Sanitary Code the sale of oysters so fattened can be prevented.

A Discussion of the Milk Problem.—The first of a series of five meetings to discuss the question of pure milk, under the auspices of the New York Milk Committee, was held on Saturday, April 4. Further meetings will be held as follows: At 2:30 P.M. on April 11, 18, and 25, and at 8 P.M. on April 25. The program of the first meeting was: "The Need for Improving New York's Milk Supply," papers being read on "The Present Condition of New York's Milk Supply" by Dr. Linsly R. Williams; "Milk as a Carrier of Infection," Prof. H. W. Conn; "The Relation of Milk to Infant Mortality," Dr. William H. Park. On Saturday afternoon, April 11, the subject for discussion will be "Tuberculosis." Papers are announced on "Milk as a Carrier of Tuberculous Infection," Dr. E. C. Schroeder; "State Legislation on Bovine Tuberculosis," Mr. Stephen G. Williams; "The Relation of Bovine Tuberculosis to

the Dealer," Dr. E. M. Santee. On Saturday afternoon, April 18, the topic will be "Methods for Improving the Supply." Papers will be presented on "Health Department Methods," Dr. William C. Woodward; "Sanitary Methods," Mr. Harry Bramley; "The Dealer's Attitude Toward Health Department and Sanitary Methods," Mr. Loton Horton. On Saturday afternoon, April 25, "Pasteurized Milk" will be discussed. The papers to be read are: "The Effect of Heat Upon Milk and Upon the Bacteria in Milk," Dr. Milton J. Rosenau; "Pasteurized Milk as a Food for Infants," Dr. Henry Koplik; "The Attitude of Public Authorities Toward Pasteurized Milk," Mr. Ed. H. Webster. At the evening meeting of the same day the discussion will be on "Certified Milk and Other Clean Raw Milks." Papers will be presented on "Certified Milk," Mr. Walter W. Law, Jr.; "Safe Raw Milk at a Moderate Cost." Dr. Charles E. North; "New York City's Future Milk Supply," Dr. Henry Dwight Chapin.

Prevention of Tuberculosis.—The Illinois State Board of Health recently issued a circular comprising sixty pages of printed matter, which serves as a practical guide for the consumptive and his associates. The title of the little pamphlet is "The Cause and Prevention of Consumption." The subject matter is presented in lucid and simple language, so that it can be easily understood by those of limited education.

A New Hospital for the Tuberculous.—The people of Cook County on April 7 will vote on a bond proposition, which will include plans for a new hospital for the treatment of the tuberculous, to be built by Cook County. The present institution at Dunning, Illinois, is to be turned over to the State. According to recent information, during 1907 and up to March 28, 1908, the Cook County institution cared for 2,805 out of approximately 8,000 tuberculous patients of the county. Of the 350 tuberculous patients now being cared for by Cook County, 40 are quarantined at the poorhouse, owing to the fact that beds elsewhere are unavailable.

Psychopathic Ward for Hudson River State Hospital.—A ward especially for cases of incipient insanity is to be established at the Hudson River State Hospital at Poughkeepsie. It is to have accommodations for eighty patients and a free clinic will be run in connection with it. The patients in this department are to be admitted and discharged with as little red tape as possible and without any legal commitment. It is expected to introduce the same system in the State institutions at Binghamton, Middletown and Utica.

New Ration for the Army.—The President has signed an order to take effect May 1 providing a new army ration. The principal change is in the garrison ration, to which are added butter, milk, spices, flavoring extracts, lard and baking powder. The additions will increase the daily cost per man by from 22 to 25 cents.

Bill Against Unauthorized Embalming.—Mayor McClellan has signed Coroner Harburger's bill to prevent the embalming of the body of any person dying under suspicious circumstances without the permission of a coroner. The penalty for violation of the provisions of the bill, which becomes a law immediately upon the affixing of the Governor's signature, is imprisonment for a term not exceeding one year, or a fine not exceeding $500, or both fine and imprisonment.

Institute for Tropical Medicine in Australia.—*Science* states that it is intended to establish an institute for tropical medicine at Townsville, in Northern Queensland. The general management will be undertaken by the three Australian universities having medical schools—Sydney, Melbourne and Adelaide. The federal government of Australia has agreed to subsidize the work at the rate of £450 per annum, and the government of Queensland will give £250; and these sums will be increased by private subscriptions. The managers of the Townsville Hospital will set aside a building for a laboratory, free of charge.

A Society to Protect Scientific Research.—The committee established under the leadership of Professor Starling to assist the British Royal Commission on Experiments on Animals, now that it is no longer required in its original form has been organized into a society called the Research Defence Society, having for its object the dissemination of knowledge about experiments on animals and opposition against antivivisection. The society, whose membership already includes many eminent scientists and physicians, intends to supply information, send speakers to debates, publish articles, etc.

Dr. Robert Koch arrived in New York on Tuesday of this week. He will remain here several days and will be a guest at a number of entertainments planned in his honor. On Saturday, April 11, he will be entertained by the German Medical Society at a dinner at the Hotel Waldorf-Astoria.

Professor S. E. Chaillé of the Tulane University medical school at New Orleans has been awarded a pension under the Carnegie foundation for retiring professors. Professor Chaillé is seventy-eight years of age and was graduated from Harvard University in 1851. For many years he has been professor of physiology and comparative anatomy and dean of the faculty.

Osteopaths and Death Certificates.—The acting Corporation Counsel of the city last week delivered an opinion to the Board of Health in which he construed the law passed last year by the Legislature in regard to osteopathy as not according to osteopaths the right of registry with the Board of Health for the purpose of signing death certificates. He recommended, however, that the question should be brought before the courts for decision by mandamus proceedings. Such proceedings have been begun in behalf of a Brooklyn practitioner of osteopathy who last February sent a death certificate to the Board of Health which was not accepted.

Christian Science and Diphtheria.—A Boston Christian Scientist died last week of diphtheria after having refused to allow medical care for herself or her husband and two children, all of whom had the disease.

Measles on a Transport.—The United States transport *Thomas* arrived at Manila on April 4 with fifty cases of measles on board. The *Thomas* is the second transport to arrive within a month with measles and mumps among the recruits on board.

New York Academy of Medicine.—At the meeting of the Academy of Medicine to be held on Thursday, April 16, a discussion of various aspects of exophthalmic goiter will be conducted by Drs. Louis B. Wilson of Rochester, Minn., W. S. Halsted of Baltimore, and Alfred Stengel of Philadelphia. On Thursday evening, April 30, there will be held a public meeting at which the Hon. Rufus B. Cowing will make some remarks on the value of medical expert testimony. At this meet-

ing the president and the members of the State and New York City Bar Associations will be invited to meet the Fellows of the Academy and the medical profession at large.

The American International Congress of Tuberculosis and the Medico-Legal Society of New York.—The American International Congress on Tuberculosis and the Medico-Legal Society of New York, meeting in joint session, will hold the sixth American International Congress on Tuberculosis at the city of Chicago, Illinois, on June 1, 2, and 3, 1908, under the presidency of Dr. Charles H. Hughes of St. Louis, Mo. The secretary of the congress is Dr. Juan J. Ulloa, 66 Beaver street, New York City.

Six Counties (Miss.) Medical Association.—At the semiannual meeting of this organization held in Clarksdale on March 25, the election of officers resulted as follows: *President*, Dr. Backstrom, Tutwiler; *Vice-Presidents*, Dr. Glass of Coahoma County, Dr. L. L. Bankstrom of Tunica County, Dr. J. S. Sanders of Tallahatchie County, Dr. Alexander of Quitman County, and Dr. T. J. Allen of Bolivar County; *Secretary*, Dr. J. W. Gray, Coahoma; *Treasurer*, Dr. L. D. Harrison. The next meeting will be held in Clarksdale in December.

Lincoln County (Ark.) Medical Society.—At the recent meeting of this organization the following officers were elected: *President*, Dr. J. F. Johns; *Vice-President*, Dr. W. C. Kimbro; *Secretary and Treasurer*, Dr. C. C. Price.

The American Therapeutic Society.—The ninth annual meeting of this society will be held in Philadelphia, May 7, 8, and 9, 1908, under the presidency of Dr. John V. Shoemaker of Philadelphia. The secretary is Dr. Noble P. Barnes of Washington, D. C.

California State Medical Society.—This organization will hold its annual meeting in San Diego, April 21, 22, and 23, 1908.

Iowa State Medical Society.—The annual meeting of this society will be held in Des Moines, May 20, 21, and 22, 1908.

Obituary Notes.—Dr. Edwin Porter of Northfield, Vt., died of pneumonia on March 19 at the age of eighty-two years. He was born in Northfield, and was graduated from the University of Vermont in 1850, and three years later received his medical degree from Dartmouth University. He at once began practise in Northfield, and at the time of his death he and his father had practised in that town uninterruptedly for ninety-two years.

Dr. A. P. McConnell of Ludington, Mich., died on March 24 at the age of eighty-two years. He was born in McConnellsville, N. Y., was graduated from the Ohio Medical College at Cincinnati in 1850, and practised in Pontiac for twenty-three years. He served as surgeon in the Twenty-second Michigan Volunteer Infantry. In 1872 he settled in Ludington.

Dr. Joseph F. O'Connell of Brooklyn died in Montclair last week after a long illness at the age of fifty years. He was born in Newark and was graduated from Bellevue Medical College at the age of twenty-one years.

Dr. Albert B. Robinson of Roxbury, Mass., died on March 29 at the age of seventy-three years. He was born in Pelham, and in 1857 graduated from the medical department of the University of Buffalo. For the next five years he practised in Amherst, but soon after the war broke out he entered the service as surgeon and continued until the close of the war. Since that time he had practised in Roxbury.

Dr. Edward G. Morse of Roxbury, Mass., died suddenly on March 24 of heart disease while talking to a patient. He was born in Roxbury in 1848 and was graduated in medicine from Harvard University in 1870, since which time he had practised in his native town.

Dr. William Pinkney Bridgham of Buckfield, Me., died on March 21 at the age of ninety-one years. His father was Dr. William Bridgham, Buckfield's first physician.

Dr. Harry M. Crossland of Dexter, Me., died of appendicitis in Worcester, Mass., on March 24 at the age of twenty-seven years. He was a graduate of the Maryland Medical College in Baltimore.

Dr. Wilbur Gillett of Detroit died of cerebral hemorrhage on April 1 at the age of fifty-six years. He was graduated from the medical department of the University of Michigan in 1879.

Dr. John C. Spear, a retired surgeon of the United States Navy, was killed in a runaway accident at Norristown, Pa., on April 3. He was born in 1839, and was graduated from the medical department of the University of Pennsylvania in the class of 1861.

Dr. William J. Pennington of Brooklyn died on March 30 at the age of forty-two years. He was graduated from Albany Medical College in 1891 and for ten years had been connected with the Department of Health.

Dr. Augustus C. Kinney of Astoria, Ore., died of carcinoma in Oakland, Cal., on March 24, at the age of sixty-three years. He was a native of Iowa and received his medical education in the Bellevue Hospital medical school. He had practised in Astoria for thirty years.

Dr. Charles J. Orr of St. Louis died on March 28 at the age of forty-one years. He was born in Louisiana, Mo., and was graduated from the St. Louis Medical College in 1891.

Dr. Wm. L. Orr, formerly of Ottumwa, Ia., died in Malden, Mass., on April 1 at the age of eighty-four years. He was a native of Washington, Pa., and after graduating in medicine from the Jefferson Medical College in Washington began practise in Ottumwa, where he resided for over fifty years. During the Civil War he served as surgeon in the Twenty-first Iowa Infantry.

Dr. Absalom Pettit of New Orleans, La., died on March 16 at the age of sixty-eight years. He was born in Warren County, Miss., and received his medical degree from the University of Louisiana in 1870. He was one of the organizers of the Orleans Parish Medical Society, and was well known for his work in the prophylaxis and treatment of yellow fever.

Dr. Dwight Flower of Monticello, Wis., died on March 19 at the age of sixty-eight years. Dr. Flower was born in Bennington County, Vt., and received his medical education at the Albany Medical College. He practised for a time in Buchanan County, Ia., and later removed to Monticello. A little over a year ago he retired from active work.

Dr. William P. Bridgham of Buckfield, Me., died on March 21 at the age of ninety-two years. He was a son of Dr. William Bridgham, one of the early physicians of Buckfield, and was graduated from the Medical School of Bowdoin College. For over fifty years he was an active practitioner, but about twenty years ago he retired.

Dr. Granville A. Harlow of Tyngsboro, Mass.,

died on March 10 at the age of fifty years. He had practised in Harpswell for ten years, removing to Tyngsboro in 1891. He was graduated from the Medical School of Bowdoin College in 1881.

Dr. Edward G. Morse of Roxbury, Mass., died suddenly on March 24 at the age of sixty years. He was graduated from Harvard Medical School with the class of 1870, and at once began practice in Roxbury, in association with his father. He was a prominent member of numerous medical societies, in which he had held many official positions.

Dr. George Linville Baker died at Philadelphia on March 24 at the age of twenty-eight years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1906, and he was recently temporary resident physician at the Pennsylvania Hospital.

THE MIDDLETON GOLDSMITH LECTURE.

The Middleton Goldsmith lecture of the New Pathological Society was delivered at the Academy of Medicine on Saturday evening, April 4, by Professor Frank B. Mallory of Harvard University, the subject being "The Results of the Application of Special Histological Methods to the Study of Tumors."

The present paper, the speaker said, was really a continuation of a study which he had published in 1905, entitled "Contributions to the Classification of Tumors." A great deal of information had been obtained by the application of two new staining methods, namely, the phosphotungstic acid hematoxylin stain, and the anilin blue connective tissue stain. By means of these, the fibrils of certain cells were distinctly stained and easily recognized. In practically all instances, the tissues were placed into Zenker's fluid, for fixation, within two seconds after the removal of the tissue from the body. This was extremely important in studies of this kind. Certainly the use of these stains had simplified the histological classification of tumors; the speaker recognized that such a classification had its drawbacks, but at the present time an etiological classification was not yet possible. The methods about to be discussed were not really new, but consisted rather in the more rigid application of well-known procedures, together with the use of a few new staining methods.

The speaker next described the ordinary fibroblast, and spoke especially of the two kinds of fibrils demonstrable with his stains. These were (1) fibroglia, rather straight fibrils developing in the body of the cell, and staining blue with the phosphotungstic acid hematoxylin stain, and (2) collogen fibrils, rather wavy fibrils lying between the cells and staining pale red under the same conditions. The arrangement, size, appearance, and distribution of these fibrils gave important clues concerning the tissue which was being studied. Professor Mallory then took up in some detail the various types of sarcomata, and described the appearance of the cells and fibrils as shown by means of the new stains. In connection with myxosarcoma, he said that there was little reason for placing this in a class by itself; it should be regarded as a variety of fibroma or of fibrosarcoma.

Turning then to smooth muscle cells, the speaker described the peculiar fibrils associated with these. These cells possessed coarse fibrils, the so-called myoglia fibrils, which were apparently limited to the cells to which they belonged. Surrounding the cells were also collogen fibrils. The appearances were so characteristic, that tumors belonging to this class were easily recognized.

Cells of neuroglia tissue occurred in two forms, namely, glia cells, and ependyma cells. Tumors belonging to this class had been so well described, the speaker said, that he would limit his remarks to two cases in which the differential methods of staining had been of great value in fixing the nature of the tumor. Professor Mallory then described a case in which a tumor had developed over the region of the coccyx in a woman 45 years old. The tumor produced metastases in different parts of the body, and after several operations caused the death of the patient. In the gross, the appearances were those of a sarcoma, but histological examination had shown that the tumor was a carcinoma. The remarkable part of this was that fibrils were present in large numbers in parts of the growth, between the cells filling the alveoli. The tumor was apparently developed from the gland tissue present as the remains of the neural canal, which can often be demonstrated as late as the fourth month of embryonic life.

The speaker said he had little to contribute to our knowledge of epithelial tumors, though here too the phosphotungstic acid stain had been very useful. He had found that the cells of the stroma of a carcinoma often showed more than a study of the epithelial cells themselves. In this connection, he spoke of the carcinomata which had been said to have turned into sarcomata. In one such case which had come under his observation, he believed that the tumor was really an embryoma with but slight differentiation of the cells.

Passing on to the endothelial tumors, Mallory gave his definition of endothelium, and stated that there was little to characterize such tumors. However, they showed up well in contrast with the tissue already described. The endotheliomata were divisible into three groups, namely, blood-vessel endotheliomata, lymph-vessel endotheliomata, and dural endotheliomata. He gave a detailed description of each class, and described also two cases of tumors of the lymphangiomatous class. These were quite rare.

There were three points, the speaker said, which this study had brought home to him. (1) It was important to study carefully each kind of normal cell by means of the above-mentioned methods so that this cell could be easily recognized wherever it was met with. (2) It was important to determine which was the essential cell in each kind of simple tissue, and to name the tissue accordingly. (3) It was advisable, in naming tumors, to do away with all terms referring to accidental features, such as "round cell," "spindle cell," "myxo-," etc.

After this discussion, Professor Mallory demonstrated a series of lantern slides, illustrating the various points which had been touched upon. One of the striking pictures thus shown related to a case of endothelioma. The patient was a girl 16 years old, whose right hand showed a large deformed tumor-like mass. From this extensions had taken place up the arm, and especially about the elbow and axilla. According to the speaker, these secondary growths were not metastases, but direct continuous growths, probably through the veins. A similar case had been described by Esmarch, and that surgeon had operated on his case some twenty or thirty times, finally bringing about a cure.

Skirts and Disease.—The death rate of the city of Prague is 42 per 1,000, owing principally to its bad water supply. As trailing dresses are believed to contribute to the dissemination of germs, a general prohibition against long skirts is being enforced.

Correspondence.

TREATMENT OF MORPHINE ADDICTION.

To the Editor of the Medical Record:

Sir:—In the entirely unauthorized reports which the newspapers recently gave of my demonstration of the efficacy of a method of treatment of the morphine habit so many inaccuracies occurred and so many misstatements were made that I think it best to publish my plan of treatment at once rather than to wait, as I should have preferred to do, until I had time to tabulate my cases and to demonstrate the value of the method privately to those specially interested in the subject. There is always danger that the general employment of any new treatment by the inexperienced may result, through neglect to observe some minor detail, in failure, and so this premature publication may, I fear, bring discredit upon a method which I am confident is, if properly used, truly a specific for the cure of morphine addiction.

The following are the formulæ employed:

No. 1.—Compound extract of colocynth, 1 grain.
Extract of hyoscyamus, 1-4 grain.
Extract of nux vomica, 1-12 grain.
Extract of jalap, 1-2 grain.
Podophyllin, 1-6 grain.
Oleoresin of ginger, 1-8 grain.
Calomel, 1 grain.
Mix and make one pill.

No. 2.—Pilocarpine hydrochloride, 1 grain.
Fluid extract of hyoscyamus, 2 drams.
Fluid extract of prickly ash, 2 drams.
Tincture of belladonna root, 4 drams.
Dose: 7 to 20 drops every hour.

No. 3.—Tincture of gelsemium.
Dose: 5 to 20 drops every two hours.

No. 4.—Tincture of strophanthus, 1-2 dram.
Tincture of nux vomica, 1 dram.
Tincture of convallaria, 2 drams.
Tincture of cactus grandiflora, 2 drams.
Tincture of digitalis, 3 drams.
Dose: 7 to 8 drops every 4 or 5 hours.

The following are the general directions for the employment of these remedies, but I need hardly remind you that every patient is a law unto himself in therapeutics, and that the physician must watch the case carefully all through the treatment, and modify the dosage and the intervals of administration, according to the indications. Self-treatment is, of course, hazardous and impossible of success. Even the physician will obtain much better results after he has had some experience and has learned to recognize the signs indicative of success or failure in the action of the remedies, and how to interpret the indicatons presenting themselves in the course of the treatment.

The usual dose of the accustomed drug is to be given at bedtime, along with three pills (Formula No. 1). In the morning, after *free* movement of the bowels, give another dose of the accustomed drug. If the bowels have failed to move, give a hot water enema or a saline laxative. Within one hour after the morning dose of the accustomed drug, give 10 to 15 drops of Formula No. 2 and continue giving No. 2 every hour. Twelve hours after commencing No. 2 start giving Formula No. 3, about 12 drops every 2 hours. When No. 2 has been given for 14 hours, give three pills (Formula No. 1); continue No. 2 and No. 3. After No. 1 has acted *freely*, give a moderate dose of the accustomed drug. Continue No. 2, but stop No. 3 for 8 hours after the last dose of the accustomed drug, then resume No. 3 as before. Twelve hours after the last dose of the accustomed drug give three pills (Formula No. 1) and when these have acted freely and show greenish or yellowish discharges, discontinue Nos. 1, 2, and 3 and start with Formula No. 4, about 8 drops every 4 or 5 hours. Continue this for several days. When greenish or yellowish discharges appear the cure is effected. Should the patient become nervous or restless, give 25 drops of Formula No. 3. If the bowels are slow, assist with a saline, hot water enema, or castor oil. If, about the time for the last dose of Formula No. 1 to act, the patient becomes nauseated, give plenty of warm water and induce vomiting; it will give relief. If aching of the bones occurs, give a hot bath. If sleep does not come by the second night, give bromides or trional. Watch the pulse throughout the treatment.

C. C. Langsdorf, M.D.

253 East Eighty-Sixth Street.

UTERINE DISPLACEMENTS.

To the Editor of the Medical Record:

Sir:—I wish to say a word in reply to Dr. Frank H. Hancock relative to a "Plea for the Correction of Uterine Displacements," published in your journal of March 7, 1908. In the first place, what is the normal position of the uterus? It is perfectly mobile—like the testicle, sigmoid, enteron, arm, or leg. What is uterine displacement? It is fixation. A dislocated uterus is a fixed uterus. The uterus is dislocated or fixed in general by three means—peritonitis, myometritis, splanchnoptosia. A testicle is dislocated, fixed, by epididymitis. The uterus has no definite position except a mobile one; it continually moves. If the normal uterus is perfectly mobile, anatomically and physiologically, why should it be fixed, *i.e.* dislocated? A fixed uterus is pathological and will be insulted, injured in its function (sensation, absorption, peristalsis, secretion, menstruation, gestation). The "pexyite," examining a uterus fixed by a pelvic peritoneal exudate quickly announces that the uterus is dislocated and should be released. The next woman he examines with the uterus, however mobile, lying on the rectum he exclaims it is retroverted, dislocated, and must be fixed, which is substituting or adding a pathological state. Loose mobile testicles require no fixation, neither does the subject with the loose testicle seek fixation. In fact, the layman would not consider loose or mobile testicles dislocated—though the scrotum extend well distalward. The enteron is mobile, loose. Does it require enteropexy? The uterus should not be fixed that is pathological. Hysteropexia is not required; it is an unnatural, unnecessary, harmful operation. *Uncomplicated retroversion requires neither surgical nor medical aid.*

In 532 subjects Hancock had 147 retrodisplacements—then he would operate on 26 per cent. of women patients. I examine numerous patients in whom the uterus lies against the rectum who complain of no pelvic symptoms. The uterus is a pelvic organ, anatomically and physiologically, and should not be forced proximalward to be fixed in the abdomen and to the abdominal wall—the fixed uterus is compromised in function, circulation, and nerve supply (sensory and motor). As the normal uterus is always moving, and hence possesses no fixed position, the operator assumes considerable preconceived conceit in selecting a solid, immobile uterine position. The word "displacement" is unfortunate, as it introduces ideas in the patient's head with no compensatory value. Displacement must mean dislocation or it is a misnomer. Dislocation means permanent fixation.

Dr. Lucy Waite and myself made experiments on the cadaver to demonstrate the position of the uterus by injecting the rectum or bladder with air. Such experiments demonstrated an extensive variation or deviation of position regarding the uterus. However, marked deviation of position of an organ cannot be viewed as pathological. For example, in some 800 personal autopsic abdominal inspections I noted that the sigmoid flexure was a pelvic organ in some 75 per cent. of females and 65 per cent. of males. It was in the left iliac fossa in perhaps 20 per cent. and an abdominal organ in perhaps 10 per cent. But such marked deviations of position are not "displacements" nor dislocations; they belong to the natural mobile range of the organ, and sigmoidopexy should not be performed, as it would compromise the sigmoid function (sensation, peristalsis, absorption, secretion) and circulation.

Again as regards the uterine support, we should remember that the uterus is supported by every thread of tissue which extends from the uterus to the pelvic walls and adjacent viscera. The pelvic floor must also be viewed as a uterine support, with similar relations as the abdominal wall has to other viscera. The pelvic floor should be repaired like hernia in any other segment of the abdominal walls. As to Alexander's operation, it is an unnecessary, harmful, unnatural operation and should become obsolete. The round ligaments do not support the uterus—and can be but forced substitutes, *i.e.* pathological. If one opens the abdomen the round ligaments may be observed to be slightly relaxed—not suspending or supporting the uterus. If the round ligaments are forced into a primary uterine support they will elongate and the woman will require an Alexander operation about as frequently as a man will need his hair clipped. The Alexander operation is a hygienic operation at high risk and cost. Subjects with uncomplicated uterine retrodeviation practically do not suffer symptoms from it.

When symptoms arise with the uncomplicated retrodeviation they are from the nervous system or other detectable and non-detectable sources.

Dr. Hancock assumes matters too serious surgically. His "symptoms" tend to surgery—to "scalpel storms." The doctor may remember that blood cures disease, that the control of blood volume to any viscus is secured by means of anastomosis or inosculating circles, and that if he will induce the uteroovarian artery or the genital vascular circle to conduct increased blood volume to the genitals the vast majority of gynecological patients will be satisfactorily cured—with no genital pexy for future reference. Surgeons have gone mad, diagnosis and medical treatment are becoming buried, obscured in surgical technique. The post mortem is useless, forsooth, because diagnosis must be made in the living by abdominal incision and direct vision. The mechanical surgeon has arrived with his commercial tool chest, the cutter with his "scalpel storms" is multiplying rapidly, surgery is becoming a commercial by-word, the "pexyite" is abroad in the land, the suspicion of the people is beginning to arise from the slaughter of the mechanical surgeon.

A plea for correction of "uterine misplacements" is a direct bid for surgery which in general is not only unnecessary but harmful. Of the general causes of "uterine misplacements"—myometritis, splanchnoptosia (relaxation of uterine supports)—who is sufficiently irrational to advocate fixing a myometritic uterus as a sensible method of treatment? Of the "uterine displacements" from peritonitis, the cause of the displacement must be treated—the peritoneal adhesions must be absorbed, dissolved. Eighty per cent. of adult females possess peritoneal genital adhesions. In subjects of general "uterine displacements"—myometritis, peritonitis, splanchnoptosia—the first two simply require ample blood volume for cure; the last, the splanchnoptotics, certainly require no uteropexy, fixation, but rather repair of the pelvic floor. Hysteropexy is considered a short road to success; however, it is not only irrational, but accompanied by disorders, physiological (compromising of function), anatomical (compromising of structure), and pathological (substituting one alleged pathological state, displacement, for another). Fixing the uterus or uteropexy does not invite extra blood to the genitals, because fixation compromises the uterine function and consequently circulation and nourishment. Irrational surgery is debased surgery; it is a misapplication of art. Unnecessary surgery is criminal, harmful surgery; it injures patient and physician—creates misery.

If the uterus be "displaced" by myometritis, the most rational and successful treatment is by enticing blood to the genitalia—hyperemia. This we know has been accomplished for centuries by (1) hot douche, (2) massage, (3) medical tampon, hygroscopy, (4) intrauterine applications, (5) menstruation, (6) gestation, (7) electricity. Uterine hyperemia absorbs the exudates accompanying the myometritis, in decreasing the intense hpyertrophic myometritis and increasing the uterus in atrophic myometritis, which is a frequent disease. The treatment for uterine "displacements" due to peritonitis certainly as a general proposition demands not surgery. The indicated treatment is to absorb the adhesions or results of peritonitis. The basic treatment for pelvic peritoneal exudates is hyperemia to promote absorption—it is practically similar to the treatment for myometritis, *i.e.* an attempt to direct extra volumes of blood to the genital organs through the genital vascular circle (uteroovarian artery). Surgical treatment for pelvic peritoneal exudates is practically not for the purpose of fixing the uterus, but to release it from fixation in order that it may be free, mobile, and that its functions may continue uncompromised by fixation. The treatment for "genital splanchnoptosia," *i.e.* alleged excessive genital mobility, exaggerated "uterine displacement" possesses scant recommendation when its representative is the irrational hysteropexy. For genital splanchnoptosia the surgical treatment, if required, is in repairing the pelvic floor, not in fixing any of the genitals any more than one would fix loops of enteron in splanchnoptosia. Suspension of the uterus is secondary to its supports; the uterus is suspended by peritoneum, ligaments, vessels and nerves, connective and elastic tissue.

The supports of the uterus are the primary and essential factors for study. The uterine supports are the pelvic floor (*i.e.* the diaphragma pelvis rectale, the rectal muscle group, and diaphragma pelvis urogenitale—the pudendal group of muscles). The gynecologist is not merely a surgeon any more than the oculist, neurologist, etc. The specialist or gynecologist is the one who should understand disease of the genital tract and the relation of the latter to adjacent visceral tracts. His judgment should be exercised in favor of what is beneficial for the patient. All irrational, unnecessary, and harmful operations should cease, as hysteropexy, Alexander's operation, and the cruel, brutal, senseless uterine curettage (except for diagnostic purposes). Ovariotomy had its day, as well as trachelorrhaphy and clitoridectomy, and now let the other unnecessary, irrational, and harmful gynecological operations pass into deserved oblivion.

Because a woman becomes well subsequent to a gynecological operation affords no proof that she required the operation. She might have been a neurotic. Because dealing with neuroses (not disease) Dowie reported numerous recoveries.

Byron Robinson.

TREATMENT OF CHRONIC ENDOMETRITIS.

To the Editor of the Medical Record:

Sir:—I note with interest an article in your issue of March 28, 1908, entitled "A Rational Method of Treatment in Chronic Endometritis," by Dr. Joseph M. Rector. He says: "Taking as a basis for my work a paper written by Dr. A. H. Goelet and read before the Gynecological Section of the American Medical Association in 1899, I have *perfected* the treatment which I shall here describe." (Italics mine). This statement promised a great deal, and I am always interested in and glad to commend any advance made in the treatment of gynecological conditions. But after a careful perusal of the paper I find that in every respect the treatment described is that advocated by me, even the iodine intrauterine irrigation, and not modified or "perfected" in any detail whatever. The mechanical construction of Dr. Rector's irrigator is the only item of difference. And whether this is an improvement or not is a matter for discussion.

A. H. Goelet, M.D.

New York

OUR LONDON LETTER.

(From Our Special Correspondent.)

SLEEPING SICKNESS—THE NATURAL CURE OF CANCER—MALIGNANT DISEASE OF THE CECUM—MEDICAL SERVICE OF ASYLUMS BOARD.

London, March 20, 1908.

The second International Sleeping Sickness Conference has terminated without the delegates coming to an agreement on the Draft Convention. The French and Italian plenipotentiaries were unable to accept the proposal made last June and then unanimously recommended for the establishment of a central bureau in London, though the German members strongly supported the plan. Other points were also objected to by the French plenipotentiaries, and though the majority of the powers favored them it was thought useless to proceed further in the absence of unanimity. Lord Fitzmaurice, in closing the proceedings, said the position was the same as at the conference on Egyptian finances in 1854. Here agreement was not possible, but the next year a solution was found. This, he thought, was a happy augury that the present assembly of distinguished scientific men and the discussions which had taken place would help to form opinion, and he hoped much could be done by separate conventions and ultimately a central bureau established for combating the disease. The Lord Mayor entertained the president and plenipotentiaries at luncheon on Monday.

The conference having failed, a meeting of the African Society to hear a paper on the subject by Colonel David Bruce was particularly opportune. This took place, as previously fixed, on Tuesday evening, the chair being taken by Sir West Ridgeway, who recalled Colonel Bruce's achievements, especially his latest discovery of the cause of Malta fever, which had had the happiest results on the health of the Mediterranean stations. Colonel Bruce, whose lecture was illustrated by many lantern slides, said that sleeping sickness had been known on the west coast of Africa ever since those parts had been explored, but was long looked upon as a pathological curiosity rather than as a disease with great power for evil, such as it is now known to be. It was first observed in Uganda in 1901 and the common theory was that it was brought there by Emin Pasha's Soudanese soldiers and followers, some 10,000 in all, who settled at Busoca. The proved facts were that it was caused by a small blood-parasite, a trypan-

osome, something like that which was carried from animal to animal by the tsetse fly; that the fly took the trypanosome from the blood of wild animals and passed it on to horses and that if trypanosomes were injected into the blood of a monkey it suffered from sleeping sickness. In Uganda the distribution of the disease and of a particular tsetse fly were the same, and that fly flourished only on the part of the lake shore where forests and deep jungle growths were near. The fly required clear water and forest. The natives held their markets with the islanders on the edge of the lake and so were bitten by the tsetse as they lay on the shore. Sleeping sickness was spreading, owing to the demand for native labor, and was a menace to the opening up of Central Africa. At present it seemed certain that the disease was only carried by one species of tsetse fly—the *Glossina palpalis,* so that the *Glossina morsitans,* which was found more south, in the Transvaal and Rhodesia, did not threaten those countries. Professor Koch's theory that the chief food supply of the *Glossina* was crocodile's blood required proof. *Glossina palpalis* existed where crocodiles did not, and in the laboratory, it fed on any animal food offered. As the fly could only live where there were dense forests near to clear water, good work might be done by clearing trees near the great ferries of the lakes. As to cures, Colonel Bruce said there was not a single well-authenticated instance of cure of the disease in man and all attempts to render him immune by an antitoxic serum had completely failed.

The natural cure of cancer was the subject of Professor Handley's Hunterian lecture at the College of Surgeons on Friday. He began by saying the spread of the disease in the body was mainly by means of a process of tendril-like growth along the lymphatic vessels—a "process of permeation." Referring, then, to recorded cases of spontaneous cure of fully developed cancer, he said that, though such cases were extremely rare, complete natural cure was not an exceptional event, as shown by what is called "atrophic scirrhus." As to records of incomplete natural cure, illustrated by the disappearance of the original growth or its satellite nodules, the lecturer said retrogressive processes occurred normally in cancer, so that there was nothing anomalous in cases of natural cure. Lymphatics along which cancer cells had grown were ultimately converted into fibrous cords, in which no cancer cells could be traced. Particles of growth arrested in the lungs were destroyed in a similar way. Large masses of cancer tended to degenerate from their center to their circumference, and ultimately were replaced by a fibrous scar containing no cancer cells. The process of repair began in the oldest part and spread centrifugally, but it rarely overtook the growing edge of permeation and was, therefore, usually ineffective in saving the patient's life. It was a purely local process, depending on degeneration of the cells, and did not indicate blood-immunity, such as was found in fevers. Nevertheless, the recognition of this natural mode of cure may have valuable results. The lecturer regarded it as absolutely certain that many so-called remedies for cancer owed their reputation to misinterpretation of the results of the natural process of repair. Nothing, he declared, had yet been discovered which could replace surgical measures. There was some evidence to show that, even in cases where the growth could not be completely removed, nature might be enabled, through the operation, to deal successfully with the remainder. The natural mode of cure involved destruction of the lymphatic vessels and consequent destruction to the flow of lymph. As an instance, extremely painful swelling of the arm was frequent in mammary cancer.

Mr. Handley then mentioned that as a result of his work in the Middlesex Hospital research laboratory, he had devised a simple operation for the relief of the condition. This consisted in draining the swollen arm by a number of buried silk threads, which carried away the excess of fluid by capillary attraction. He compared the attitude of the public to cancer research to that of a man who sowed wheat in October and expected to reap in January. In contrast with that was the indifference of the pure scientist, for whom absolute intellection was the ultimate goal. Pending the achievement of larger results by methods still in their infancy, he was glad to be able to produce a minor instance of the immediate fruition of cancer research.

The concluding Lettsomian lecture was devoted by Mr. Charters Symonds to malignant disease of the cecum. Operative measures, he said, were very satisfactory, even when large portions were removed, the lymphatic infection being slow to occur and extension delayed. He advocated early operation in suitable cases, but it must be remembered that the disease had often been in existence long before any sign of obstruction or a tumor arose. The first part of the large intestine was particularly suitable for resection on account of the length of the mesentery, and the satisfactory condition in which the parts could be left, as in joining the ileum and colon the functions practically remained undisturbed. There were two cardinal signs of malignant disease of the cecum, viz., intestinal colic as an early symptom, and a tumor which is movable, hard, well-defined, and so close to the adominal wall that it can be grasped in the hand and lifted forward. It can also, from the position of rest, be pushed downward, swinging inward toward the median line. Upward it takes a more vertical course. Again, it can be moved directly inward toward the umbilicus, when a gurgle is often heard. The range of movements may naturally be limited by fixation of the growth, and the degree of mobility of the cecum may vary somewhat in different individuals, but, taken together, the points named would not be met with in other tumors in the region. When the disease began in the ileocecal valve, colic would precede the appearance of a tumor, but if above the valve colic might be absent. The colic was of brief duration, attended with gurgling and often with vomiting without nausea, so that a meal which had been interrupted might be returned to. The pain of the colic at first is central, but afterward settles in the cecal regions.

As to diagnosis, Mr. Symonds remarked that the mobility of the tumor and an appearance of health might prove deceptive. A suppurating growth might resemble appendicitis, a point illustrated by two cases, in one of which the sinus had healed. Sudden pain in the iliac fossa, with high temperature and a lump, had in two cases been the final signs of malignant growth of the cecum The tumor formed by tuberculous glands is smaller and fixed, and there is no obstruction. Actinomycosis may in the late stage resemble malignant growth, but in the earlier stage rather suggests a calcareous concretion on account of its hardness, fixation, and persistence.

With regard to the limits of operation, Mr. Symonds said, of course, resection was out of the question when secondary deposits were present. But slight infiltration of the anterior abdominal wall did not always absolutely forbid operation. He had once removed an infiltration scar, the result of a former operation, together with the cecum, but recurrence took place after a brief interval. Adhesion and infiltration of small intestine might not altogether forbid extirpation. Pallor indicated that the patient was unfit for a long operation, for it was probably due to disseminated growth—a true cachexia—or to small hemorrhages, as in gastric carcinoma or necrosis in the growth. When this last was the cause, removal might be successful on a very vigorous patient. Mr. Symonds uses a small Murphy's button for the junction of ileum and colon and places a row of Lembert's sutures round the junction, and surrounds the parts, whenever possible, with great omentum. He recommends postponement of anastomosis when the contents of the bowel are septic, and mentioned two fatal cases in support of this view. When palliative treatment by anastomosis was carried out, he saw no necessity for dividing or otherwise occluding the ileum below the junction. That plan would only determine an accumulation of feces in the colon, between the growth and the junction.

Service with the asylums has long been unpopular with the profession. The dearth of candidates was considered at the board's meeting on Saturday, when it was stated that certain rules were largely responsible. A committee had dealt with these and recommended some changes. The first was that requiring annual re-election of assistant medical officers after three years' service. Another required an officer receiving a visitor to notify the clerk immediately and making a charge for any refreshments supplied. No such regulations existed in other asylums, and the committee recommended their withdrawal. After discussion, the regulation as to re-election was rescinded, the other being referred to the general purposes committee for further consideration and report.

Bacteria on Trailing Skirts.—In a recent lecture, Professor Bottomley of London said that a piece of cloth cut from a trailing skirt worn by a woman walking about the West End streets was found to harbor 16,500,000 bacteria, including many tubercle bacilli.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 26, 1908.

Dental Caries as a Cause of Other Diseases.—L. W. Baker concludes a well-illustrated paper as follows: Dental caries, or tooth-rot, is the most prevalent disease that attacks man, and is a preeminent factor in the causation of other diseases in the human body. This initial disease is the cause of great physical suffering, to check which many millions of dollars are annually spent in this country. Thus, to prevent dental caries would be a great financial saving, and a very great step in preventive medicine. Since this disease is a problem of the civilized world, it should be further investigated; and to aid investigation money should be provided to secure the most eminent men in research work. In the present state of scientific knowledge, the most adequate means of combating dental caries and oral sepsis is by the enforcement of hygienic measures. In order to make his hygienic fight successful, the physician and the surgeon should cooperate with the dental practitioner, for this branch of hygiene requires a thorough knowledge of the teeth and their adjacent tissues. Skilled dentists, therefore, should be placed upon the various hospital staffs to treat this infected area which so materially hinders both surgical and medical treatment. Dentists should give the nurses instruction in the hygienic care of the teeth. Dentists should also be placed upon the staff of medical inspection of the public schools, for the condition of the child's mouth is just as important to its health as the condition of its throat and nose.

Idiopathic Dilatation of the Colon.—E. H. Stone reports one case of this unusual condition occurring in a man of fifty-six years. There is in this malady an apparently innate tendency to dilatation independently of any discoverable cause. There is no scybalous accumulation, no atony, no paralysis. Many cases develop in apparently healthy persons, and at autopsy the bowel wall is found hypertrophied. The genesis of this disease may be interpreted in two ways: According to Mya, the dilatation and hypertrophy are inborn (megacolon), while according to Generisch, only an abnormal length and abnormal course are hereditary, following which the dilatation and hypertrophy arise as secondary factors. Nothnagel and Coucetti on the other hand believe the idiopathic dilatation to be due to an inborn weakness or partial defect of the muscularis in the lowest part of the large gut, with a secondary hypertrophy of the portions above. The condition causes a greatly distended abdomen with high-grade constipation. Patients are generally males and most commonly children. Symptoms are such as would be suggested by the existence of a greatly distended gut. The most important point of differential diagnosis is that relating to intestinal obstruction. Treatment is either medical or surgical. The former will prolong life but will not cure. Of surgical procedures, artificial anus, and resection of the dilated bowel, have been proposed and successfully performed with permanent relief of all bowel disturbance.

New York Medical Journal, March 28, 1908

The Relation of Mental Attitude to Bodily Function.—W. L. Conklin believes that imagination produces not only functional disturbance but even organic changes if these disturbances are long continued. The same effects may follow long-continued exercise of the intellect, the emotions, and the will. Thought, either conscious or unconscious, precedes and gives direction and character to bodily function. As physicians we give too little attention to psychotherapy. By this term the author does not refer to hypnotic suggestion, which in his opinion has a very limited field of usefulness as a therapeutic resource, but to the practical application of the plain, common-sense fact that right thinking, a normal, healthful mental state or attitude, is conducive to continued bodily health and a potent remedial agent when bodily health is below the normal standard. He wishes to place emphasis on the fact that just as *bodily* attitude does not mean the position of the head or an arm, but of the body as a whole, so *mental* attitude refers, not to the will or the emotions, but to the mind in its entirety. What is the trend of a man's thought? Can he use his intellect and as a rule reach conclusions which are definite and reasonable? Are his emotions and imagination under control and is his volition strong? Has he an object in life and some sense of personal responsibility or is he aimlessly drifting? These are questions which have a distinct bearing upon the bodily function and health of any individual. An intelligent recognition and application of the principles involved in the relationship of mind and body is of great value in the scientific treatment of disease. It is not so easy as to prescribe veronal and valerian, but more lasting results may be looked for. Moreover, the patient who has been taught something regarding the importance of mental attitude in its relationship to health will be less in danger of a repetition of his present painful experience, and preventive measures must always be regarded, both from a scientific and from a philanthropic standpoint, a long step in advance of those which are palliative or curative only.

The Influence of Animal Therapy Upon the Opsonic Index of Tuberculosis.—Five clinical histories are given by G. B. Sweeney. In a previous issue of this journal (December 7, 1907), the author described the clinical results obtained in tuberculous patients, following the administration of a lymph derived from a bullock which had previously been rendered immune to tuberculosis. Of the five cases here reported, the opsonic index was raised, and the general condition vastly improved in four. The fifth patient, in which, at the commencement of treatment, the index was as low as 0.68, did not respond in any way to the serum, and at the time of the report was failing rapidly. Daily injection of the serum in dosage of 10 minims was employed as a routine treatment in all the cases. The author believes that the benefits obtained were due as much to the invigorating influence of the lymph upon the phagocytes as to its specific antitoxic action upon the tubercle bacilli.

The Blood Conservation of Neurotic Individuals.—J. G. Drennan notes the occurrence of an extreme degree of pallor in certain persons who are exceptionally active, and who are said, in common phrase, to "live on their nerve." But the blood of these same neurotics is not the blood of an anemic person, however much in other respects they resemble one another; but the pallor of the one is not the pallor of the other; that of the neurotic is due to the absence of blood in the capillaries of the skin, and not, as in the anemic, due to the presence in them of a blood poor in corpuscles. This blood circulates in the superficial capillaries of his skin and gives him the typical pasty, sometimes rosy, puffy appearances of the anemic; while, on the other hand, the neurotic has empty capillaries in his skin. It has been scientifically demonstrated that if his skin is pricked with a needle no blood issues from the puncture, showing that there is an absence of blood in the capillaries of the skin, while in the case of the anemic a thin, watery, reddish fluid issues, denoting the presence of a poor quality of blood. The neurotic is a shrewd individual; whether consciously or unconsciously, so one cannot perhaps say, though experience shows that in many respects he is consciously so; though probably in this one respect it is unconsciously that he regulates his blood supply for his own best interests. Nature wisely attempts to make a good use of the small amount of blood which such a person manufactures, normal in quality, but subnormal in quantity, and, therefore, not sufficient for all the requirements of the body. To thus economize, she restricts the flow to the skin, allowing merely sufficient to maintain the skin in a condition of living, not of health, however, for the skin is tough and leathery, due to poor vascular supply; but it furnishes a covering for the body, even if its other functions are not performed. The bulk of the small blood supply of the body in these cases is sent to the most vital structures, and they are maintained in a fair degree of health, and to all appearances the person performs the ordinary, and sometimes extraordinary, duties of life as well as his more robust-looking brother. Very often considerable of this scant supply goes to the brain and spinal cord, and a well-nourished nervous system, even if it be in a neurotic person, regulates the other systems. His efforts may be spasmodic, but generally they are fit for the occasion. Never despair of one of these pallid workers flunking his duty, when necessity or ambition make demands upon him. The proverbial pallor of the hard student is accounted for in this same way; the bulk of his blood supply going to nourish his brain. There is, on the other hand, the rosy neurotic, less often seen, who is also anemic, and to whose skin considerable blood is supplied; there is not in this case the conservatism of the other, nor is the blood of such good quality. The skin in the pallid case is rather a foreign covering, and not the true covering of a human body.

Journal of the American Medical Association, March 28, 1908.

The Importance of Ophthalmoscopy.—E. Jackson emphasizes the importance of the use of the ophthalmoscope in the study and diagnosis of disease, outside of the specialty of ophthalmology. He points out the specially favorable opportunities afforded by the eye for pathological

observation, giving, at it does, the means of direct inspection of the most delicate mucous membrane in the conjunctiva, of the effects and repair of injury in the cornea, of lymph spaces and channels, and of unstriated muscle in the anterior chamber, and iris, and of the nutritional and other changes of a modified epithelial tissue in the lens. It is through the ophthalmoscope, however, that ophthalmology is able to bring its greatest contributions to general medicine. The revelations of the Roentgen ray, he says, compared to those of the ophthalmoscope, are as the groping among twilight shadows to clear vision in strong sunlight. Not only do we see things with the ophthalmoscope, but we see them clearly, and we see them with the magnification of a good working microscope, and we see them alive. Passing with simple mention the vast number of conditions of cerebral, and general, and local disease, in regard to which the ophthalmoscope gives important information, Jackson takes up, to illustrate his points, the changes in the vessel walls and the retinal circulation that are so readily studied by the ophthalmoscope, and says their importance is not sufficiently appreciated by the profession at large. We are also able to study with the ophthalmoscope the results of lesions of related organs through the nervous and vascular connections of the retina and by the disturbances of the field of vision. The lesions of the eye have peculiar importance with reference to general pathology and general diagnosis, and the time will come when the observation of the ocular circulation is deemed as important as that of the pulse in the diagnosis of disease.

Infant Mortality in the Summer Months.—S. E. Getty gives an account of methods by which the infant mortality from digestive disorders in Yonkers has been reduced 50 per cent. within the last twelve or fourteen years. This has been accomplished by securing a better milk supply, tenement inspection, educational methods with both physicians and parents as regards infant feeding, etc., but the most effective measure of all, in Getty's opinion, was the establishment of a milk dispensary. The effect of high temperature and humidity in the summer months, has, he thinks, been overestimated, but sudden changes, especially a rapid drop after a heated term, tend to increase the number of deaths. Epidemics of measles or whooping cough in late winter or early spring also seem to have a like effect.

Nerve-bridging.—A. S. Taylor, New York city reports a case of brachial birth palsy in a child aged one year, in which a two centimeter gap after removal of a cicatricial mass in the brachial plexus was successfully bridged by loops of chromicized catgut wrapped with Cargile membrane. Power was gradually restored to the paralyzed muscles, the trophic changes disappeared to a large extent, and the flexion contracture of the fingers was also gone, so that twenty-eight and a half months after the operation the child used its arm freely, and the improvement was still progressing.

Epididymitis and Orchitis Complicating Typhoid Fever.—The rarity of reported cases of orchitis and epididymitis as complications of typhoid fever is noticed by J. G. Beardsley, who reports briefly four cases. On inquiry among physicians, he finds that these complications are by no means rare, and he attributes the infrequency of reported cases in the literature largely to a popular misconception that such complications were due to pre-existing gonorrheal infection. He shows how the typhoid bacilli can reach the organs by way of the blood stream, and through the urethra by way of the vas deferens. The 102 cases he has collected from the literature are analyzed, and his conclusions given substantially as follows: 1. Epididymitis or orchitis, occurring during typhoid fever or during its convalescence, is, in the majority of cases, due to infection by Eberth's bacillus. 2. These complications may be caused by other pus-producing bacilli, but this is unusual. 3. The conditions may also be caused by phlebitis and thrombosis of the testicular veins, due to the same bacillus. These complications may occur during the course of the disease, but are more common during convalescence. 4. The lesion, as a rule, is unilateral, but it may be bilateral, and involve both the epididymis and the testicle, or either, and not infrequently the cord as well. 5. Effusion into the tunica vaginalis testis is seen occasionally, and there may be urethritis and discharge. Localized necrosis and suppuration, with extrusion, is an uncommon termination, the usual one being resolution in a week or ten days. Treatment consists in support by a suitable suspensory bandage and the local application of cold. Opium may be used to relieve pain. If inflammation does not subside, and suppuration threatens, the ice bag should be replaced by hot applications. If pus forms, he advises incision and drainage. Very rarely, the complete disintegration of the organ may demand its removal.

Diffuse Suppurative Peritonitis.—Stuart McGuire gives a sketch of the history of the development of the now generally accepted method of treatment, which was rationally deduced from scientific observations, and consists essentially of Fowler's position and Murphy's proctoclysis; hence, it may properly be called the Fowler-Murphy treatment. Its practical steps are as follows: Open the abdomen over the primary focus of infection and correct the trouble, so that the admission of more poison is prevented. Make a second short incision just above the pubes, and insert a large rubber drain to the bottom of the pelvis. The work should be rapid, with as little disturbance of the viscera as possible, and no attempt should be made to remove the pus by sponging or irrigation. Place the patient in bed in an exaggerated Fowler's position, and give saline solution by continuous low-pressure rectal irrigation; administer morphine in small doses for pain, and spartein in large doses as a general stimulant and prophylactic against urinary suppression. Give no purgatives, but secure bowel movements by enemata. If there is much nausea and vomiting, irrigate the stomach thoroughly and withhold food until the stomach can retain and assimilate it. Since he has adopted this method McGuire has seen a great reduction in his mortality. He objects to the semi-sitting position in these cases, because: (1) It makes it difficult for the nurse to place the bedpan properly; (2) it is unnatural, and subjects the patient to mental and physical strain; (3) he will slip down when relaxed by weakness or sleep, so that his body will bend at the costal arch, and his abdomen will be parallel to the surface of the bed. For these reasons, McGuire prefers raising the head of the bed, thus getting a uniform flat inclined surface, inclined at any angle, and the patient is completely relaxed and easily nursed.

Adiposis Dolorosa.—J. B. Frankenheimer gives the history of a case of adiposis dolorosa occurring in a woman, aged seventy-seven, with pronounced mental symptoms—stupor, apathy, and loss of memory. The attack began with projectile vomiting and headache. There was a history of probable lues and of excessive sexual indulgence in early married life. Marked improvement followed the use of thyroid treatment (5-grain tablets, t. i. d.). There was no history of alcoholism. Frankenheimer reviews the symptoms, pathology, etc., of the disorder, calling special attention to its excessive incidence, proportionally, in females, the evidence of thyroid involvement, and the part possibly played by the genital organs in the production of the disease. This latter can only be ascertained, he says, by further study, but he mentions the following observed symptoms as significant: Excessive menstrual flow, uterine hemorrhage, early menopause, commencement of disease at menopause, exacerbation following abortion, inception of disease at delivery. In conclusion, he suggests that adiposis dolorosa, like acromegaly, is a dystrophy, the one affecting the fatty, the other the osseous structures; and that there is present a toxemia dependent on a dysthyroidismus, and the disturbed function of the pituitary body and the genital organs.

The Lancet, March 21, 1908.

Preliminary Note on Some Aspects of Splenic Anemia.—G. A. Gibson refers to the case of a man of thirty-six years who presented the usual symptoms. The question of splenectomy came up but it was considered wise to first ascertain the state of the bone marrow in order to determine whether any useful end would be attained by surgical intervention. Accordingly and with the patient's consent, the left tibia was trephined and a small portion of marrow removed for examination. This revealed the presence of a high degree of gelatinous degeneration without any appearance of regeneration. All idea of operation was therefore given up. The patient died about one year from the commencement of his symptoms from hemorrhages, dropsy, and exhaustion.

Obstruction Caused by Sarcoma of the Small Intestine.—The patient of A. C. Firth was a woman of 62 years who in May, 1907, was operated on for a strangulated femoral hernia on the right side. Three weeks later pain came on in the left iliac region with constipation and vomiting; readmission to hospital, October, 1907; some abdominal distention, acute pain, no tumor detectable, and some tenderness over the lower abdomen. Abdominal section revealed two bands attached side by side below to the crural ring on the right side and above, about half an inch apart, to a knuckle of small intestine. They were about one inch long and as thick as a No. 4 catheter. After division of the bands between ligatures a further investigation showed a mass resting on the edge of the pelvis. It proved to be freely movable and when brought out of the wound was found to be a growth involving a portion of the small intestine. The bowel above was much

dilated and that below contracted, so the growth was freely excised, together with a good margin of bowel and mesentery, and a lateral anastomosis performed. Recovery was slow but uneventful, and the patient was discharged in the latter part of November with the obstruction entirely relieved. When last seen (March, 1908) she was very well and was following an active life. The specimen removed consisted of a ring growth in the lower part of the ileum. It was about one inch wide and half an inch in thickness, the maximum measurements being at the mesenteric side of the bowel. The caliber would not admit the little finger. The mesentery was not invaded and the peritoneum over the mass was normal. No enlarged glands were found at operation. On opening the intestine the growth projected into the lumen of the gut and was covered with healthy mucous membrane, no ulcerated surface being present. The tumor was sent to the clinical laboratory and under the microscope it proved to be a typical round-celled sarcoma. On receiving the report the patient was carefully examined with a view to finding, if possible, evidence of sarcoma elsewhere, but none was discovered.

Deaths Under Anesthetics.—Speaking of facts brought out by the official reports to the Registrar-General, F. J. Waldo presents the following conclusions: (1) That present available data as to deaths during anesthesia are so imperfect as to be useless for the purposes of formal investigation. (2) That the Registrar-General's returns of such deaths are for the most part obtained from coroners' returns of deaths occurring in hospital practice. (3) That only a small proportion of deaths under anesthesia in private practice ever come to the notice of registrars or coroners. (4) That imperfect as are the returns for England and Wales, those of Scotland and Ireland are still less trustworthy. (5) That with such imperfect data it is impossible to form any trustworthy conclusions as to the absolute rate of fatalities to administrations, or to the relative proportion of deaths to administrations in the case of particular anesthetic drugs. (6) That it is highly desirable to arrive at satisfactory conclusions as to the precise facts of all deaths under anesthesia both for the safety of the public and the furtherance of scientific knowledge.

Do Fleas Spread Cancer?—V. G. Webb reports the case of a woman of 58 years who had been in the habit of visiting another woman suffering from advanced rectal cancer. On one of the last evenings of November, 1907, while sitting by the woman's bedside, she was severely flea-bitten on the right breast. On December 2, she showed the author the breast in which she had not previously noticed any alteration. The skin was hotter than over the left breast and was slightly inflamed, and the whole breast looked like that of a woman on the third day after delivery, except that the nipple was a little retracted. The diagnosis was interstitial mastitis, and the breast was bandaged over a pad soaked in glycerite of belladonna. After about a week's treatment all external signs of inflammation were gone, and the breast was nearly its normal size; but in a few days it had enlarged again, though not nearly to the same extent. There was very little pain and the size kept fluctuating. In the second week of January last the swelling became more localized in the upper and outer segment. Rubbing with ointment of iodide of lead was tried and there was a slight discharge of blood from the nipple. On February 1 a diagnosis was made of obstruction of ducts by papilloma and congestion. On February 17 the patient was admitted to the hospital and on the 18th the entire breast and a gland which was enlarged were removed. The patient made a very quick recovery. The naked-eye appearance of the growth confirmed the diagnosis of papilloma. On microscopic examination the growth showed in parts simple papilloma, but in others the papillary growths had malignant characters—*i.e.* the case proved to be duct carcinoma. The gland showed no malignant characteristics. It seems possible that the whole trouble has been due to the flea-bite inoculating cancer germs. Of course this may be wrong and the growth immediately after may have been only a coincidence, but it seems worth while testing whether inoculation can be produced in this way. The points to be emphasized are: (1) that the patient was bitten by fleas from the bed of a cancer patient; (2) that there followed an inflammation (though it was not necessarily *post hoc propter hoc*); and (3) that after about a fortnight a definite growth developed, ending in duct carcinoma.

British Medical and Surgical Journal, March 21, 1908.

The Local Treatment of Diphtheria.—J. T. Maclachlan extols the merits of the hourly application of a mixture of Liq. hydrarg. perchloridi and glycerite of tannic acid in equal parts. He advises its use every hour, night and day, until the membrane is gone, and then at intervals for a week or longer, until the swab test is negative. One illustrative case is detailed. [The stirring up of a case of diphtheria every hour, night and day, for any purpose whatever, smacks more of the Middle Ages than of the year of grace, 1908. Abstr.]

A Case of Syphilis, Phthisis, and Locomotor Ataxia.—The patient of H. G. Sutherland was a man of forty-six years. The title explains the case. In regard to the effect of syphilis on phthisis, the author states that all authorities admit that the former predisposes to the latter. If the phthisis breaks out during the secondary specific period, it runs a rapid course, but later the malign influence of the latter malady is greatly lessened. In the case under consideration the lung lesion did not appear until twenty years after the specific infection, and is now running a chronic and benign course. Evidences of sclerosis are found also in the condition of the arteries, although there are no signs of aortitis or nephritis; and also in the condition of the spinal cord. It is little wonder, then, in an area of the lung where the tissues not only share the general incitement to sclerosis, but are also subject to the irritation of the tubercle bacillus, that fibrosis should be active. Further, there is little doubt but that the active hyperemia in the pulmonary lesion, present during "periods of high blood pressure," will also augment this process. Thus syphilis, one great cause of arteriosclerosis, whereby life is shortened, affords a slight reprieve from a disease which might otherwise have been fatal. With regard to the course of phthisis following syphilis, it appears to be true that the more ancient the syphilis the more hopeful the prognosis.

Münchener medizinische Wochenschrift, March 17, 1908.

Tuberculin Reactions.—Heinemann compares the results obtained by means of the conjunctival reaction and the method by inunction recently described by Moro. The patients tested by the former procedure were one hundred and forty-four in number, of which forty-eight were tuberculous, thirty-three suspected, and sixty-three not suspected. Of the first group, eight gave negative reactions, of the second, eleven were negative, and of the third, fifty-three. Of the nonreacting tuberculous persons, five were in the first stage of the disease, and three in the third stage. The author, therefore, concludes that the method may, in some cases, be unreliable as a diagnostic procedure. The inunction test was applied in sixty-six cases after a previous conjunctival test, and by itself in one hundred and eight other cases. The results obtained in this way lead Heinemann to believe that in adults the inunction method is at least as useful as the eye reaction, while it has the advantage of not giving rise to undesirable consequences. In performing the conjunctival reaction cases of conjunctivitis were encountered often lasting two weeks, while the patients were never annoyed in any way by the inunction. The preparation used for the latter purpose was a fifty per cent. ointment of old tuberculin in lanolin.

Blood Platelets, the Coagulation of Blood, and Rigor Mortis.—Bürker has continued on muscle the investigations previously conducted by him on the clotting of the blood. As the result of these, it appears that the coagulation of blood is dependent on the disintegration of the blood platelets, and that chemical substances of various sorts influence the process of coagulation in the same way as they do the disintegration of these structures. The behavior of the leucocytes and red cells seems to be without importance. Experiments on the isolated sartorius muscles of frogs show that substances which inhibited the disintegration of the platelets, and showed coagulation, also stimulated muscle, and caused it to contract. Muscles treated in this way remained more or less translucent, whereas control muscles became opaque and whitish. Muscles prepared in the former way stayed translucent when placed in alcohol or formalin, a fact of significance as regards the fixation of specimens. It also appears that the salts of calcium are of importance both in blood coagulation and in that of muscle.

Suicide in Italy.—The latest statistics on suicides in Italy show that the number in 1887 was 1,449, in 1903 it was 1,922 and in 1904 it was 2,156. Of these 2,156 the males numbered 1,705 and the females 451. Firearms were the most frequent means of suicide, the deaths by that method numbering 522. Of the other suicides, 433 were by drowning, 388 by hanging, 213 by precipitation from heights, 188 by poison, 98 by asphyxiation, 68 by cutting instruments and 62 by crushing under vehicles.

Book Reviews.

THE COMMONER DISEASES OF THE EYE. How to Detect and How to Treat Them. For Students of Medicine. With 280 illustrations (many original) and eight colored plates. By CASEY A. WOOD, M.D., C.M., D.C.L., Professor of Ophthalmology, Northwestern University; Ophthalmic Surgeon to St. Luke's Hospital and Wesley Hospital, Chicago; Consulting Ophthalmologist to Cook County Hospital and Passavant Memorial Hospital; ex-Chairman of the Ophthalmic Section, American Medical Association; formerly President of the American Academy of Medicine and of the American Academy of Ophthalmology and Otology, Mitgleid der Ophthalmologischen Gesellschaft, etc., and THOMAS A. WOODRUFF, M.D., C.M., L.R.C.P. (Lond.), Ophthalmic Surgeon, St. Luke's Hospital and St. Anthony de Padua Hospital, Chicago; Member Ophthalmic Section, American Medical Association; Fellow of the American Academy of Medicine; Fellow of the American Academy of Ophthalmology and Oto-Laryngology, Mitglied der Ophthalmologischen Gesellschaft, etc. Third edition, enlarged and improved, with index. Chicago: W. T. Keener & Co., 1907.

THIS is the third edition of this work, somewhat enlarged and well illustrated, to which two entirely new chapters have been added. The first hundred pages are devoted to the anatomy of the orbit and eyeball. Then follows a chapter of thirty-four pages on "Methods of Examination of the Eye." The optical features of the eye are then considered, after which the diseases of the eye in their logical sequence are described and treatment is given. Chapters are devoted to "Ophthalmology in General Medicine and Surgery," and to "The Ocular Complications of Certain Systemic Diseases," "Headache from Eye-strain," and "The Commoner Diseases of the Eye Muscles" are each accorded a chapter. A feature somewhat unusual in books of this kind is a chapter on the relation of nasal and neighboring cavities to diseases of the eyes. A chapter on remedies in ophthalmic practice completes the work.

The subject is presented in a brief, succinct manner, well adapted to the uses of the student and general practitioner.

STUDIES FROM THE DEPARTMENT OF NEUROLOGY of Cornell University Medical College. Vol. II. New York City, 1907.

PROFESSOR DANA deserves much credit for inaugurating the custom at the Cornell Medical College of reproducing in one volume the noteworthy writings of members of his department during the year. This second volume comprises fourteen clinical and pathological studies, six of which are by Dr. Dana, who also outlines in the introduction, the organization, methods, and work of the department.

INSTRUCTION POUR LE TRAITEMENT PAR L'HYPERÉMIE du Dr. SCHMIEDEN, chirurgien en chef de la Clinique de l'Université de Bonn, traduit par Mme. FORTOUL. Préface de M. le Professeur agrége TUFFIER Paris: Vigot Frères, 1907.

THIS little brochure contains a very brief and very practical set of instructions as to the use of Bier's methods of hyperemia. The various procedures are described in sufficient detail to enable any practitioner to apply them with the aid of a few illustrations which have been inserted in the text. The indications for the use of the method are also briefly explained.

DIE IMPOTENZ DES MANNES. Von Dr. ORLOWSKI, Spezialarzt in Berlin. Würzburg: A. Stuber, 1907.

IN this pamphlet of 78 pages the author summarizes in a very practical way the causes, pathology, symptoms and treatment of impotence. He lays particular stress upon the etiological significance of an hypertrophy of the verumontanum, which he treats by applications of silver nitrate through the endoscope.

FUNCTIONAL NERVOUS DISORDERS IN CHILDHOOD. By LEONARD G. GUTHRIE, M.A., M.D., F.R.C.P., Senior Physician at Paddington Green Children's Hospital; Physician to the Hospital for Epilepsy and Paralysis, Maida Vale. London: Henry Frowde, Oxford University Press; Hodder and Stoughton, 1907.

THE book comprises chiefly lectures and addresses, some of which have appeared in the *Clinical Journal*, and in Allbutt's "System of Medicine." The author modestly disclaims all pretensions to scientific treatment of the subject, and states that his object has been in the line of preventive medicine, to lessen the prevalence of neurasthenia in the rising generation by emphasizing the truism that the neurotic child is the father of the neurasthenic adult. In the introductory chapters he describes the necessity of acquiring a knowledge of the personality, ancestry, and environment of the child, and describes at length the neurotic or emotional temperament, which, he says, is a matter of inheritance, and manifests itself largely by a nervous instability peculiar to the individual, and shown in disorders of coordination, defective control of higher over lower centers, etc. The author considers most functional neuroses to be of psychical origin. His chapters on hypersensitiveness of the special senses, morbid fears, the disorders of sleep, moral failings, and mental and educational overstrain, are all interesting and suggestive and sprinkled with illustrative examples. Some of the remaining subjects treated are: "The Disorders of Dentition," "Spasmodic Affections," "Chorea," "Tics," "Delayed Walking," "Hysterical and Functional Paralysis," "Defects of Speech," and "Idioglossia." The book is entertainingly written and contains much to enhance the physician's knowledge of childhood, and should enable him to treat understandingly many of the functional disorders of children which were left almost entirely, until recent years, to the disciplinarian.

INTRODUCTION À LA THÉRAPEUTIQUE NATURISTE par les Agents Physiques et Dietetiques. Par le Dr. Fernand SANDOZ. Paris: Steinheil, 1907.

IN this thesis which constitutes a volume of 260 octavo pages, Sandoz reviews the various "natural" systems of therapeutics. In an introductory section he deals with the fundamental principles which should guide the physician who aims to cure by "natural" methods, *i. e.*, through the agency of physical and dietetic factors. Next the "natural" therapeutics of some acute diseases, typhoid, influenza, scarlatina, appendicitis, rheumatism, etc., are considered. The main portion of the book is, however, devoted to the "natural" treatment of chronic diseases. Here are considered in turn the systems of Priessnitz and of Kneipp (hydrotherapy), the "air cure" of Rikli, the dry diet cure of Schroth, the methods of cure by vegetarian diets, by means of curdled milk, by Bier's method, etc. Schroth's system seems to be the author's favorite, as he devotes much space to it and goes into a great deal of detail concerning its technique, its action, and its results. The author is a pupil of Bouchard, who asserts that in chronic diseases it is necessary to accelerate nutritive processes. This Schroth's cure does to the author's satisfaction. The views are opposed by von Noorden and his school, who deny that in chronic diseases, *e.g.* in gout, there is a slower rate of nutrition. Dr. Sandoz predicts a great future for "natural" therapeutics and asks that these methods be taken out of the hands of quacks and applied scientifically.

DIE EXPERIMENTELLE DIAGNOSTIK, SERUMTHERAPIE, UND PROPHYLAXE DER INFEKTIONSKRANKHEITEN. Von Stabsarzt Prof. Dr. E. MARX. Zweite Auflage, mit zwei lithographischen Tafeln. Berlin: August Hirschwald, 1907.

PROF. MARX has compiled in a small-sized volume all the important data of experimental diagnostic, sero-therapeutic, and prophylactic methods that are at present either in general use or about to be adopted. The book is intended specially for health officers and for military surgeons, who desire a short practical treatise on these subjects. He begins each disease with a discussion of the leading facts concerning the specific germ thereof, *i.e.* date of discovery, cultural and morphological characters, etc. Then he considers the sero-diagnostic and sero-therapeutic methods thus far developed for each disease, and finally speaks briefly of the prophylactic measures. Exact information is given as to the technique and the sanitary officer with the army in the field, etc., will find a useful guide in this book when he comes to deal with an epidemic. The book is up to date, save that it contains but brief references to opsonins. It is to be regretted that the work is not illustrated.

A HANDBOOK OF SKIN DISEASES AND THEIR TREATMENT. By ARTHUR WHITFIELD, M.D. (Lond.), F.R.C.P., Professor of Dermatology at King's College, etc. New York: Longmans, Green & Co., 1907.

WHITFIELD'S book is a short manual on dermatology intended for students and practitioners. Much attention has been therefore paid to the clinical descriptions and the methods of treatment of the most common skin diseases. For the first time in a text-book of this kind there has been incorporated some material derived from the investigations of Sir A. E. Wright, which are applicable to the diagnosis and treatment of skin diseases. Some attention is also paid to the microscopic diagnosis of parasitic and bacterial skin affections, simple methods of examination being described in the appendix. Nothing is said, however, of the methods of staining and searching for the spirochæta of syphilis.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 20, 1908.

DR. ABRAHAM JACOBI, CHAIRMAN PRO TEM.

THIS meeting was held under the auspices of the Section on Neurology and Psychiatry, one of the newly formed sections.

The Development of the Modern Care and Treatment of the Insane, as Illustrated by the State Hospital System of New York.—Dr. CARLOS F. MACDONALD read this paper. He said that at the present time there were in the State of New York fifteen State hospitals for the insane (thirteen for the ordinary insane and two for insane criminals), and twenty-three licensed private institutions for the insane. The whole number of committed insane in the public and private hospitals of the State of New York at the end of the fiscal year, September 30, 1906, was 28,302 (13,548 men and 14,754 women). The whole number of insane in the State hospitals, including two hospitals for insane criminals (960), on September 30, 1906, was 27,317. The whole number of insane in licensed private institutions was 985. The net increase for the year in all institutions was 895; in the State hospitals the net increase was 896. The number of resident medical and other officers in State hospitals was about 150, and of attendants, nurses, and other subordinate employees, 5,000. The cost of the State hospitals, for lands, buildings, equipments and furniture, represented a permanent investment of more than $26,000,000, while the average annual expenditure for their maintenance, exclusive of cost of repairs, renewals and enlargements, was about $5,000,000. The average weekly per capita cost of maintenance for the fiscal year was $3.53. Prior to the establishment of the State Lunatic Asylum at Utica the insane poor were mostly cared for in county and town poorhouses or in jails, there being substantially no other provision for them. Provision was made in the original charter of the Utica Asylum whereby patients who failed to recover after a certain period of time, or who should be pronounced incurable, might be removed to a county poorhouse upon the superintendent's certificate that the patient was "incurable" or "not likely to be benefited by further treatment, and could probably be made comfortable in the poorhouse." This was a most inhumane provision, and one that continued in operation under certain modifications until the creation of the State Commission in Lunacy in 1889, and the subsequent passage of the State Care Act in 1890. This pernicious system continued for a period of more than forty years, during which time the poorhouses became filled to overflowing with mentally afflicted human beings, who were accorded only the merest pretence of custodial care and maintained in a spirit of parsimony whose chief apparent ambition was to see on how small a pittance body and soul could be kept together. The insane were pauperized in the matter of food, clothing, shelter, and environment, as well as of proper medical care and treatment. The condition of the insane in the State of New York at that time was best described by the terms, misery, degradation, squalor, wretchedness, and neglect. He cursorily outlined the legislation for the insane in the State of New York since the creation of the Commission in Lunacy in 1889, and said that among the more important improvements as regards methods and conditions which had accrued to the institutions for the insane and their government, under the new order of things, might be mentioned the following: 1. A codification of the laws of the State relative to the insane into one comprehensive statute, known as the "insanity law." 2. A complete registration in the office of the commission of all qualified examiners in lunacy. 3. A complete registration in the office of the commission of all persons committed to institutions for the insane, both public and private. This registration already embraced about 75,000 cases of insanity, from which valuable deductions and comparisons might be made. 4. Provision for the transfer by order of the commission patients from one institution to another without recommitment. 5. The removal of patients from their homes or elsewhere by trained attendants sent from the hospitals. 6. Removal of the legal distinction between acute and chronic insanity, by designating the State institutions for the insane as "hospitals" instead of "asylums," and organizing them upon a curative basis, thus inculcating the hospital idea. 7. A regulation regarding the correspondence of the insane, which provided that any patient who desired to do so might write at least once in two weeks. Letters addressed to the Governor of the State, the Lunacy Commission, judges, or any official having jurisdiction in lunacy cases, must be forwarded unopened. 8. Provision for paroling patients, under certain conditions, for a period of thirty days, during which they might return to the hospital without recommitment. 9. A regulation requiring that patients on admission to a hospital shall be informed of the nature of the institution and of the fact that they were detained under legal commitment. 10. Affording all patients the legal right of a hearing by the visiting commissioners, apart from any officer of the hospital. 11. A rule restricting the issuing of licenses to conduct private institutions for the insane to reputable physicians of at least five years' experience in the care and treatment of the insane. 12. Provision for the clinical teaching of insanity in the State hospitals by admitting to the wards thereof under proper restrictions students of medical colleges situated in the vicinity, as well as practising physicians who might desire the opportunity of studying mental diseases clinically. 13. Provision for the appointment of medical internes in each of the State hospitals at a salary of $600 per annum, in addition to the regular medical staff. 14. A regulation requiring competitive civil service examinations for appointment of resident officers in State hospitals. 15. A material increase in the average rates of salaries and wages of all grades of service, also an increase in the ratio of medical officers, nurses, and attendants to patients, including a woman physician, on the staff of each hospital. 16. The establishment of training schools for nurses in all of the hospitals. The adoption by the hospitals of a uniform dress for nurses' and attendants' wear. The introduction of women nurses in the men's wards, such nurses to be paid the same wages as men. Also a material extension of accommodations for nurses in detached buildings, or nurses' homes, and the employment of a corps of night nurses. 17. The appointment of consulting boards for the hospitals. 18. Provision for the employment of dentists; also for examinations by eye specialists. 19. An annual allowance to each hospital for the purchase of medical books, journals, etc. 20. The employment of a chef in each hospital, in addition to the ordinary corps of cooks. 21. The adoption of a schedule of food supplies, including a per diem ration allowance of each article. 22. A marked improvement in the methods of bathing, by the introduction of "rain" or "spray" baths and other hydrotherapy. 23. A requirement that, so far as might be deemed feasible, the hospitals should enter into joint contracts for the purchase of staple articles of supply through competitive bids. 24. The abolition of mechanical restraints in all the hospitals and the substitution therefor of useful occupations, diversions, and amusements of various kinds. This was the first instance in the United States of the absolute abolition of mechanical restraint in a public institution for the insane. To-day it was difficult for those who were unfamiliar with the subject to realize that the old conditions had entirely disappeared under modern methods of care and treatment. 25. The introduction of tent life for the care of tuberculous patients in 1901 by the late Dr. A. E.

Macdonald. 26. The systematic employment of patients at useful occupations, such as farm and garden work, in the various repair shops, bakeries, kitchens, laundries, etc. 27. The establishment of a Pathological Institute. The Institute was divided into departments and the gentlemen in charge were designated associates in their respective branches, the whole being under a director. 28. The establishment of a system of after-care of the insane to prevent relapses. The progress and present status of the New York State hospital system might be regarded as a continuation, if not the full fruition, of the great reform movement in behalf of the insane, inaugurated more than a century ago, by Pinel in France, by Tuke in England, by Jacobi in Germany, and Rush in the United States. This splendid system was a living monument to unselfish effort for humanity and science. The principle of State care was founded on a broad basis of science and humanity, when intelligently applied, as it was in the State of New York to-day.

Dr. Wm. Mabon, superintendent of the Manhattan State Hospital, opened the discussion. As the result of the institute work, uniform methods of clinical study and laboratory research were adopted, and it seemed desirable to report the method of clinical study and case recording in the New York State hospital system. The methods now used at the Manhattan State Hospital represented those in use in other State hospitals. The Manhattan State Hospital was divided into two divisions, one for women, the other for men, and in each division there was a reception service to which patients were admitted when they came to the hospital. In each reception service there was a staff of four or five physicians working under the direction of a second assistant physician. For a time the physician made physical examinations only, after which he was given cases in which to work out the mental symptoms as well. The following classification had been formulated by Dr. Meyer, the director of the Pathological Institute: Brain tumor, traumatic psychoses, psychoses accompanying other nervous diseases, senile psychoses, general paralysis, alcoholic psychoses (perhaps with subdivisions into types), morphinism, cocainism, etc., infective-exhaustive psychoses (delirium types), allied disorders, depressions not sufficiently distinguished, symptomatic melancholia, depressive hallucinations, involution melancholia, allied disorders, paranoiac conditions, dementia præcox, allied disorders, manic depressive psychoses (first, second, third, fourth, etc., attack), allied disorders, constitutional inferiority, hysterical insanity, epileptic insanity, imbecility and idiocy, not classified. Staff meetings were held in the two divisions each week day morning, and the members of the staff were given the opportunity to express an opinion as to the advisability of discharge, etc. In addition to the regular week-day staff meetings, a staff meeting was usually held on the third Tuesday evening of each month, at which cases were presented and original papers discussed. Recently considerable attention had been given to the prolonged bath treatment of cases of insanity, a treatment that was inaugurated by Dr. Dent. This treatment increased the excretions from the skin, kidneys, and bowels, increased the appetite, and had largely taken the place of sedatives. The patients remained in the tub from a few hours to several weeks if necessary.

Dr. Frederick Peterson, ex-president of the New York State Commission in Lunacy, called attention to what they had not done for the insane. A book might be filled with praise for what had been accomplished, but they might also fill a book with criticisms on conditions as they were. What were they doing in the way of prophylaxis? It had been estimated that nearly 20 per cent. of the insane under State care owed their insanity to alcohol, a preventable cause. That meant nearly 6,000 patients in this State in round numbers, and it meant an annual loss to the State through alcoholic insanity of about $2,400,000. There still existed among the people an ancient legacy of feeling about an asylum, and they passed it as they did a prison or a cemetery with a mixed dread and mistrust. Out of this they should be educated. They must learn that insanity was an illness, a preventable and a curable one. The period of detention in general hospitals or psychopathic hospitals should be at least ten days instead of five, and without any magistrate's or judge's order whatever. This was purely a medical and not a legal matter. It was a question for the Board of Health to regulate, not the courts. It should fall altogether under the rules of quarantine. An insane person was sick. The Lunacy Commission reported overcrowding every year, and the responsibility for this rested with the Legislature. Only one new hospital for the insane had been built in eighteen years. In the report of the Lunacy Commission for October 1, 1906, the excess of patients in the hospitals over the estimated capacity was 1,812; even though the 1,812 excess was not there, there would still be overcrowding. There should be money appropriated for the construction of new asylums. Some 16 to 17 per cent. of the admissions were of people between 60 and 100 years old, and a considerable proportion of them were not insane. They were physiologically senile or dotards. Besides being overcrowded, the State hospitals were inadequately supplied with physicians. The proportion should be at least one physician to 150 patients. The number of nurses and attendants was also inadequate. There was a form of psychotherapy that was far from sufficiently developed; patients should be occupied in various exercises and occupations. In 50 per cent. of the twenty-three institutions of a private nature, the standard of care was scarcely equal to that of the State Hospitals. There was not the same painstaking, scientific study of the cases; there was not the same ambition to excel and progress, and no systematic occupation of patients. Within two or three years, chiefly through the efforts of Miss Louise Schuyler of the State Charities Aid Association, an after-care association had been formed. This work should be extended to all parts of the State, and it should include among its functions fore-care or prophylaxis as well as after-care.

Dr. Chas. W. Pilgrim, President of the State Commission in Lunacy, said that he would bear witness to the great changes that had taken place in the care of the insane since the organization of this commission in lunacy. One who had been in the service for twenty years certainly could appreciate the changes that had taken place, and how important they were. The Commission in Lunacy had had many obstacles to overcome, and the first commission had succeeded, due to the personnel of that commission. So soon as the import of the first document was recognized the passage of the State Care Act, the removal of the insane became assured, but the present system was by no mean absolutely perfect. The passage of this act had been brought about by the efforts of the State Charities Aid Association, the work of which was supplemented by the Commission in Lunacy. He believed that when the history of the insane in the State of New York had been written, two names would appear very prominently, those of Dr. Carlos F. MacDonald, and the Hon. Goodwin Brown.

Dr. Albert Warren Ferris continued the discussion. By order of the New York State Commission in Lunacy, licensed private houses for the care and treatment of the insane were allowed to receive voluntary cases, as well as those committed under the insanity law. In 1788 there was placed upon the statute books of this State "An Act for Apprehending or Punishing Disorderly Persons," which gave authority to two or more justices of the peace to apprehend and lock up dangerous insane persons in some secure place, who, if such justices should find it necessary, should be there chained. In 1873 Dr. John Ordronaux was appointed Commissioner in Lunacy to fill a newly created office. No actual ruling as to voluntary patients

seemed to have been made till November, 1891, when the new Commission, headed by Dr. McDonald, formulated a special document. Dr. Ferris called attention to Section 445 of the Penal Code, under the title, "Maintaining Private Insane Asylums," and to Section 47 of the insanity law, and the amended chapter 497, laws of 1905. There seemed to be a desire among a certain class of physicians to place patients quietly and secretly in the custody of even unskilled and improper persons, that they might keep such patients in their hands for a longer period than they would otherwise be able to do, and thus secure an additional income from such sources. Instances occurred in which insane patients, who were improperly placed in hotels without proper watchful supervision, and perhaps after a mistake in diagnosis, had committed suicide. The question as to when a patient was properly a voluntary patient was a vexed one. A properly voluntary patient, he believed to be one who understood to some extent his psychosis, in so far as to know that he was ill, and also understood that the house to which he was taken was for the treatment of ill people and was willing to stay. All possible facilities should be afforded to voluntary patients who sought treatment in order to prevent their drifting into graver forms of mental disturbance. There seemed to be but one way to safeguard the insane and to foil the attempts of the unscrupulous. All insane cases of any degree should be notified. The insanity law did not contain such a provision, but it would seem that legislation to this end was desirable. Psychiatry was still in its infancy. The best methods of treatment for the insane were not yet known. The efforts that were now being made to prevent insanity by studying conditions, food, occupations, education, environment, and ancestry, etc., would lead to the saving of many valuable lives not only, but also to the restoration at an early day of hundreds of mentally shattered individuals to their position in the community as self-supporting or, at least, partially self-supporting citizens, to enjoy life, liberty, and the pursuit of happiness.

The Hon. Mr. Goodwin Brown compared the hospital system of to-day with what it was years ago. In 1899 the world of the insane was in chaos, was void, and without form. It was a fortunate thing in this world that every crisis had brought forth the man most needed to correct the evils. For a period of perhaps fifty years the insane lived to be cured by chance, or were treated practically as criminals. In 1836 this State, and other States, made efforts in a public way to alleviate the condition of these unfortunates. But these efforts were made piecemeal, and all through that period slow steps were taken; there was no formulated action. Consequently, in 1889 the care of the insane was a haphazard affair, and culminated in the creation of the State Commission in Lunacy. In all great crises the man was brought forth that was most needed. When this Commission was formed Dr. MacDonald was called at the head. If they had searched for the one man fitted for the work, they could not have found one better than the one selected. The State of New York owed a debt of gratitude to this man which could hardly be paid.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held March 17, 1908.

Dr. Onslow A. Gordon in the Chair.

The Problem of the Female Pelvis and What Can Pass Through It.—Dr. John O. Polak of Brooklyn read this paper. He said that there was no branch of medicine that had received less painstaking and conscientious attention from the general practitioner than the science of obstetrics. It was a fact that most operative cases in the gynecological service of a hospital were the result of unclean or neglectful methods on the part of the original obstetric attendant. They were an indication of lax asepsis or a forgetfulness of the responsibility on the part of the physician to repair all lacerations of the pelvic floor. As an excuse, it was frequently argued that the general practitioner was not sufficiently paid for his obstetric work, and that he could not devote the time necessary for the strict ante- and postpartum care of his patients. This did not, however, absolve the practitioner from his responsibility. It was significant that many women got well in spite of inefficient and neglectful midwifery. Moreover, there was a general tendency to ignore the responsibility which the practitioner owes to the unborn child. This responsibility was frequently violated by a general attitude of procrastination. He who did not hesitate to call in skilled surgical counsel and aid in the presence of a perforation in typhoid fever, was often ready to do a version or a high-forceps operation, alone, and even without the aid of an anesthetic. It was important that the physician should recognize readily the signs of an impending rupture of the uterus. In the presence of great difficulties preventing normal delivery of the patient, operative obstetrics, in skilled hands, offered a safe outcome. A cesarean section was no more dangerous than an operation for appendicitis. Podalic version, with the cervix dilated and the membranes ruptured, was a simple operation. It was important that the general practitioner should be able to recognize the signals that were the forerunners of dystocia. It was futile to rely on the principle that labor was a natural process. Intermarriage, civilization, and the demands of social life, had made childbirth an exceedingly difficult process with many women. In considering the question as to whether his patient was able to deliver herself unaided or not, the physician had to note the size of her pelvis, the size of the fetal head, and its ability to mould, the character of the labor pains, and the condition of the soft parts. He had to apply the methods of cephalometry and pelvimetry. It was a fact that a generally contracted pelvis was found in 2 per cent. of American-born women, and in 6 per cent. of the foreign class. In the multipara the history of previous difficult labors was suggestive of the possibility of the presence of a contracted pelvis. In a primipara the presence of a pendulous abdomen suggested a disproportion between the fetal presenting parts and the pelvis. The speaker discussed the various methods of pelvimetry and the abnormal measurements of the pelvis with the indications for interference. A normal pelvis could offer an insuperable obstruction if the head was large. If, in a primipara, the head was not engaged after the full dilatation of the cervix, then something was wrong. The practitioner's duty was to make a diagnosis of the difficulty by exclusion. It was important to examine every patient at least one month before labor; in fact, the better class of patients expected this. If any abnormality in the pelvic measurements was discovered, then the question of elective intervention arose. The practitioner was not to look upon a tedious labor with indifference. When the patient had a rise of pulse to 120 or more, a rise of temperature, edema, and thickening of the cervical ring; if the fetal heart was weak, and if meconium passed down alongside of the head; if the presenting part did not engage at the end of the first stage of labor, then it was time to think of interference. It was no credit to modern midwifery that the fetal mortality in operations requiring intrapelvic manipulation was 60 per cent. This could certainly be diminished greatly by the timely performance of cesarean section. The question of what form of intervention was best was decided by circumstances. It depended on when the patient was first seen, whether early or late, on the condition of the mother, and on the condition of the fetus. Induction of labor, if properly done, was an operation attended by little danger. If a patient was seen for the first time during labor, and a contracted pelvis was recognized, then the patient could

be given the "test of labor." During this there were to be noted the character of the pains, the moulding of the fetal head, the condition of the pulse, the height of the contraction ring, and the condition of the child's heart. If the head did not engage, the speaker advised a method of fitting the head to the pelvis by means of a modification of Müller's method. In the presence of dystocia, with a dead or dying child, an exhausted mother, and impending rupture of the uterus, then perforation of the child's head and section of the clavicle were to be considered.

Dr. Charles Jewett of Brooklyn said that many of the fatalities of the lying-in room would have been avoided if the patient had been examined at least one month before her delivery. Most practitioners were so busy that they could not take the time to practice pelvimetry and cephalometry. The speaker had endeavored to simplify the method of external pelvimetry. He believed in version more than did the reader of the paper.

Dr. Robert L. Dickinson of Brooklyn said that the primipara was to be considered guilty of a narrow pelvis until proved innocent. There was a general failure to recognize occipitoposterior positions. He alluded to the fact that the current obstetric fees were not sufficient to repay the physician for the amount and the character of the work demanded of him by modern midwifery.

The Early Diastolic Heart Sound.—Dr. William S. Thayer of Johns Hopkins University, Baltimore, Md., read this paper. He said that if the hand was placed upon the chest in the region of the cardiac apex, in young individuals whose chest-wall was not too thick, it was possible to feel a distinct, although slight, shock, independent of and following the cardiac impulse. In such persons, on auscultation, there was heard, in addition to the two usually recognized heart sounds, a third sound, occurring shortly after the second sound, and heard during the period of diastole. The third sound had the character of a dull and distant thud, occurring very shortly after the second sound and just before the cardiac pause. On palpation the accompanying shock was just perceptible to the hand. On palpation of the cardiac region there could be recognized, first, the systolic impact, second, the shock caused by the closure of the semilunar valves, and third, the impulse occurring with the beginning of the ventricular relaxation. Within the past four months, the speaker had seen twenty-four cases in which the early diastolic sound was present. It was noted in individuals who had every appearance of being normal: their pulse-rate was 60 to 80, their blood-pressure rather low than high. In some patients it was heard in the back; in all, its maximum intensity was at the apex. The third sound was associated with the shock at its point of maximum intensity. This sound was audible not only in the human heart, but also in that of the dog. In the latter, examination of the heart postmortem did not reveal any pathological cause for the sound. The explanation of the phenomenon was not clear. Examination of cardiograms and phethysmograms revealed that the third sound was coincident with the slight rise occurring in the early part of the diastolic curve, and with the shoulder of the jugular venous curve. It had been suggested that the third sound was a muscular sound, caused by an active muscular diastole. There was no evidence that this was the case. The exact time relation of the third sound to the other sounds had not yet been worked out. The third sound was also heard in various pathological conditions of the heart, as in aortic regurgitation and in mitral stenosis. The speaker's theory of the cause of the early diastolic heart sound was as follows: At the end of the ventricular contraction, with the first rush of blood into the ventricles from the auricles, during diastole, the impact of the blood against the upper surface of the flaps of the auriculoventricular valves set them in vibration. It was this vibration, the speaker said, that accounted for the third sound.

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting held Feb. 10, 1908.

Dr. Leon Louria in the Chair.

X-ray Diagnosis in General Practice.— Dr. Charles Eastmond of Brooklyn read this paper. He said that the practice of medicine was summed up in two words, diagnosis and treatment. In looking over the history of medicine, in noting its advances, and comparing the crude and inexact methods of our forefathers with the scientific and painstaking care exerted to-day, it had to be admitted that medicine was becoming more and more an exact science. Diagnosis was fundamental to all rational therapeusis. The Roentgen ray was one of the newer methods of diagnosis that had withstood the test of time. When Roentgen first announced his discovery twelve years ago many wild prophesies had been made. Some were fulfilled and some were not. With improved apparatus and technic it was now possible to discover lesions in the *x*-ray plate that formerly were not discernible. There were many pathological lesions that remained more or less obscure after the most careful clinical history and examination, and it was to the *x*-ray representation of these that the speaker particularly directed the attention of his audience. He presented remarkably fine skiagraphic illustrations of the topics discussed. It was not necessary to dwell long on fractures, dislocations and the location of foreign bodies, as physicians and the laity were familiar with skiagraphs of these conditions and appreciated their value, especially in injuries involving the joints. It was often just as important to have a plate after the reduction of the fracture or dislocation as for diagnosis, not only for the welfare of the patient, but also for the protection of the surgeon. In cases of fractures, for diagnostic purposes it was necessary to make the examination as early as possible in order that reduction might be accomplished before extensive callus formation. After reduction and immobilization of the parts, if there was any question as to the outcome, the *x*-ray examination could be made through the dressings. This involved no disturbance of the parts, but if further manipulation was necessary this could be done, using the plate as a guide. In the diagnosis of renal, ureteral and vesical calculi, the *x*-ray, in competent hands, afforded a most valuable aid. The advantage of this method over others was that it enabled one to determine the exact location of the calculus, and also for operative purposes, the number and size of the stones. No difficulty arose when there were distinct symptoms of calculus and when this was found on operation. But at times there were symptoms simulating those of stone, but on operation none was found. This was an experience of most surgeons. A carefully taken and interpreted *x*-ray plate enabled one to make a negative as well as a positive diagnosis, and the percentage of error was probably less than that of any other known means. From the fact that the situation of the symptoms and the position of the calculus did not always agree, and also that calculi were formed where least expected, an examination of the whole urinary tract was necessary. Frequently with symptoms on one side, the cause was found on the other, and additional calculi were at times found far from the apparent seat of the disease. More than one case had been seen in which a stone had been found not only in the suspected region, but others in the other kidney, in one of the ureters, or in the bladder, the second calculus giving rise to no symptoms. By taking a series of five plates, one of each renal, each ureteral and the pelvic region, it was difficult for any calculus of size to escape detection; if it did, the fault was with the operator and not with the method. The skiagraph was only a shadow picture that presented a contrast of densities in the parts examined, and errors of interpretation of the plate occurred. A mass of fibrous tissue external to the pelvis of the kidney

sometimes gave the appearance, on the plate, of a soft phosphatic mass in the pelvis of the kidney. This illustrated a possible source of error and one that was hard to overcome. Similar mistakes occurred in cases of old abscesses that had discharged and contracted down to scar tissue, unless great care was taken. In plates of the lower end of the ureters and of the bladder, a difficulty of interpretation encountered was the occasional presence of small shadows in the region of the lower ends of the ureters. Whether these were phleboliths or deposits in the muscles or ligaments of the pelvis could not be stated with certainty, but as a rule little difficulty was experienced in differentiating them from calculi in the ureters. Another problem in abdominal diagnosis was the determination of the size, position, and motility of the stomach, especially where gastropsia was suspected. This was carried out according to the methods of Holzknecht and Hulst. By giving a meal containing bismuth and then taking a skiagraph with the patient in the upright position, a distinct shadow of the stomach was obtained in its relation to other parts of the abdomen; another with the patient in the horizontal position determined its size. A subsequent examination some hours later made possible the estimation of stomach activity, and if desired, the bismuth mass could be followed throughout the intestinal tract, affording information of any part desired. When the examination was to be of the lower end of the tract, the bismuth could be introduced through a rectal tube. The orthodiagraph was nothing more than a modified fluoroscope on a large scale. By this the stomach outline could be seen, and, far more important, the waves of the stomach watched. Not since the time of Beaumont, who performed the classic experiments on Alexis St. Martin in 1822, had the opportunity arisen for such scientific observations of the behavior of food within the stomach as was observed by the orthodiagraph. The exact status of gallstone diagnosis by means of the *x*-ray had not as yet been absolutely ascertained. Numerous observers had demonstrated them at times, but they had also been missed, to be found later at operation. The difficulty of diagnosis was apparent when one considered the anatomical relations of the gallbladder, and the fact that the calculi were composed largely of cholesterin which obstructed the rays to a very slight degree. When the biliary calculi were large enough and when they contained sufficient lime salts, they would appear in the skiagraphic plate. In pulmonary tuberculosis not only could the early diagnosis be made by means of the *x*-ray, but the full extent of the lesions could be accurately determined, and exposures at intervals could enable one to ascertain whether the process was active or not. It was now possible to make the diagnosis long before consolidation had taken place, for in many cases there was found to be a thickness or infiltration of the lung tissue without discernible physical signs, and on the other hand, there were cases with pronounced physical signs that did not show the amount of tissue involvement that one would be led to suppose. Many patients were encountered who were termed tuberculous but were without physical signs in the chest. In such cases an *x*-ray plate made possible the earliest positive diagnosis, and on the other hand, definite information as to the extent of the lesion could be obtained before a patient was condemned to leave his home and business for a change of climate. The following conditions in the chest were readily recognizable in the skiagraphic plate: Pleurisy with effusion, empyema, abscess of the lung, deviations and compression of the trachea in goiter, aneurysms of the aorta, and esophageal diverticula. In examination of the accessory sinuses of the head, the results had been very satisfactory. By this means the size and condition of the frontal and maxillary sinuses could be determined to an accurate degree and the presence of foreign or pathological material demonstrated. The subject of the *x*-ray diagnosis of bone diseases was a large one, and the speaker confined himself merely to an enumeration of some of the conditions met in general practice in which the *x*-ray plate was of service to the general practitioner in making the diagnosis. These were: 1. Conditions occurring about a joint, which might be tender and painful with or without swelling; simple, acute or chronic synovitis; inflammatory osteoarthritis; infective osteoarthritis or osteitis; hypertrophic or atrophic arthitis deformans, and epiphysitis. 2. Infected wounds, particularly of phalanges; simple cellulitis without bone involvement, and cellulitis with bone necrosis. 3. Painful tender areas, usually swollen and seen most commonly on an extremity, with or without a sinus; cellulitis without bone involvement; simple traumatic or inflammatory osteitis, and osteomyelitis. 4. Bone tumors: exostoses, benign and malignant sarcomata, and cysts. In all these cases, *x*-ray examination cleared up the diagnosis when there was but little pathological involvement of the bone, and in such cases as demanded operation served as a sure and certain guide to the surgeon as to the full extent of such involvement, thus often preventing unsatisfactory results and subsequent operations. The value of fluoroscopic examinations was lessened because few men were willing to expose themselves to the full range of the rays, as was necessary in such examinations, because of the physiological effects. In the second place, the use of the fluoroscope was unsatisfactory because of the inability to maintain for even a short time the proper relation between the tube, the part under examination, and the eyes of the examiner. In addition, the personal equation was a very strong factor, and such diagnosis rested entirely upon the word of a single individual with inability to produce any evidence of the honesty of his examination. In the lighter part of the body, the arm, leg, or neck, it was possible to determine the presence of foreign bodies, and often the existence of fractures; in the chest, obliteration of the costodiaphragmatic angle on deep inspiration (evidence of pulmonary disease), and the presence of aneurysms of the aorta. But it was difficult to estimate the exact position of foreign bodies in such a way, and the existence of fractures was not always apparent, as many that had not appeared on the fluoroscope appeared later on the skiagraphic plate. Dislocations were rarely discernible, and for examinations of the head, hip, shoulder, or abdomen the fluoroscope was absolutely useless, for the skiagraphic plate presented shadows not obtainable on the screen as interpreted by the human eye.

Stated Meeting, Held March 9, 1908.

Dr. Leon Louria in the Chair.

A Case of Aneurysm of the Abdominal Aorta.—Dr. Constant Schradieck presented this specimen.

Hyperemia as a Therapeutic Measure.—Dr Adolph Bonner read this paper. He said that the empirical use of massage, the various thermal agents, and the numerous counterirritants resorted to from remote antiquity, established the fact that hyperemia had long been employed as a therapeutic measure, for the efficacy of all these agents depended upon the hyperemia they produced. It was August Bier of Berlin and his many coworkers who had placed the therapeutic use of hyperemia upon a scientific basis, and had demonstrated that it was applicable in almost every field of medicine. The physiological activity of a normally quiescent organ was associated with hyperemia of that organ. On the other hand, inflammation was hyperemia called forth in reaction to disease. The only real difference between these two forms of hyperemia was their degree, and the fact that they were produced by different stimuli. The hyperemia accompanying disease was an evidence of nature's efforts to combat disease. Instead of seeking to diminish this hyperemia, it was frequently desirable to heighten its degree by various means. A wide experience in pathology enabled Rokitansky to establish as

a dictum that pulmonary tuberculosis rarely coexisted with engorgement of the lung, such as would arise from mitral insufficiency, and that anemia of the lungs predisposed them to tuberculosis. These facts suggested to Bier the applicability of therapeutic hyperemia in the treatment of tuberculous arthritis. The principle of "Stauungshyperämie" consisted in constricting the proximal side of the diseased area so as to compress the superficial veins only, thus impeding the return flow. This became evident through the prominence of the veins and the bluish tint of the skin to the distal side of the constricting band. The engorgement of the superficial and later the deeper veins, in turn impeded the arterial circulation, so that the arteries also became dilated in order to accommodate the extra quantity of blood pumped into them. Thus, arterial or active hyperemia was established in addition to venous hyperemia. The physical retardation of the circulation hindered the free and rapid entrance of the causative factors of the particular disease into the general circulation. This ameliorated the symptoms of systemic intoxication and accounted for the rapid decrease of temperature that often occurred shortly after the application of the bandage in the treatment of acute septic inflammation. The transudation of serum that occurred into the diseased area, physically diluted the toxins and thereby reduced the intensity of their action on the various tissues. This dilution also served to facilitate the gradual absorption and consequent excretion of these noxious materials. At the same time, the antibodies in the serum diminished the virulence of the toxins. The migration of leucocytes favored an increased phagocytosis. In addition, these leucocytes formed a membrane, walling off the disease area, limiting the spread of the disease by continuity, and depriving the bacteria of new culture media. With the completion of this walling-off process, destruction of the bacteria was effected by the action of the toxins. This served to explain the demonstrable fact that virulent pus in an abscess cavity might finally become absolutely sterile. Further resolution took place by the absorption of this fluid. The cavity was obliterated by the formation of fibrous tissue or the deposition of lime. The increased vascular pressure caused the liberation of a greater quantity of blood into the devitalized tissues, a factor that was unfavorable to the existence of bacteria. Within recent years the arterial or active hyperemia had been used in the treatment of acute and chronic conditions of nonbacterial origin, for example, traumatic lesions, acute articular rheumatism, where absorption was desired, neuralgias, etc. This form of hyperemia was induced by inserting the affected area into a properly adapted box into which previously heated air constantly entered. This caused an arterial engorgement of the area thus exposed. This promoted the reconstructive powers of the tissues and facilitated the rapid absorption of exudates. The terms reconstructive, analgesic, alterative, absorbent, antibactericidal, and antipyretic could be applied to describe the manner in which hyperemia was an efficient remedial agent. For the "Stauungshyperämie," all of the joints of the arm and leg, with the exception of the hips, were amenable to this form of treatment. On account of anatomical reasons, the hip was the exception. Though the affection might be in the smaller joints of the hand or in the wrist, the rubber bandage was applied above the elbow, as was done when the latter was under treatment for the reason that constriction of the veins was thereby more easily accomplished. The veins were more superficial in the upper arm, and the bandage retained its position more readily and also gave the patient free use of his forearm. For the same reasons, the bandage was best applied above the knee for lesions affecting the leg below it. The ordinary rubber bandage, two to three inches wide and five to six yards long, was applied to the proximal side of the diseased area, with a constriction just enough to compress the superficial veins only, so that the skin to the distal side of the bandage was bluish. The bandage was not to be applied too near the lesion, nor in such a manner as to give any increase in pain. It was important that the limb under treatment should never feel cold to the touch or appear white. In chronic affections it was sufficient that the bandage remained on for an hour in the morning and an hour in the evening. In acute inflammatory diseases it could remain for a period of eight to ten hours with an interval of a few hours' rest, and the bandage was again applied. In this wise, the bandage could be worn for from twenty to twenty-two hours out of twenty-four. The period of intermission depended upon whether any edema existed or not. The rule was not to reapply the bandages before the edema had subsided; this subsidence was facilitated by gentle massage. Whether the bandage was on for a long time or not, it was best to massage the area that was under pressure so as to avoid any atrophic changes. The speaker showed by means of charts the mode of applying the bandage to various regions. For affections of the testicles a form of compression could be applied at the penoscrotal junction. For affections of the head a rubber band could be applied at the root of the neck, the amount of constriction being such as not to interfere with the respiration or speaking. Pulmonary tuberculosis was markedly influenced by the use of Kuhn's suction mask. It was worthy of mention that when such treatment was directed to diseased joints, splinting was very rarely necessary excepting where there was a tendency to deformity or when slight passive motion increased pain. Passive and active motion were to be encouraged. Within the past few years various forms of apparatus had been devised on the principle of an exhaust chamber, into which the part to be treated was inserted, and the air exhausted by means of a pump which reduced the air pressure and so established hyperemia of the part included in the chamber. These devices were costly and better suited for hospital work. In the treatment of acute and chronic localized conditions of the soft parts, such as carbuncles, furuncles, small abscesses, chronic tuberculous ulcers, and anal fistulæ, there were employed suction cups made of various sizes and shapes to fit the particular area under treatment. The treatment by means of the hot air chamber was adapted for traumatic lesions, acute articular rheumatism, arthritis deformans, ankylosed joints, lumbago, and neuritis. The degree of heat was never to be uncomfortable to the patient, and the length of time of treatment was to be an hour twice daily, with precautions against burning the skin. It was to be borne in mind that the fingers and toes could not stand as high a degree of heat as other parts. The speaker, in conclusion, said that the length of time during which Bier's treatment has been used put it beyond the experimental stage. Its theory was based upon careful experimental study and scientific principles. It was efficient in restoring functional activity in a manner that could not be obtained by means of other forms of treatment. If the technic was properly carried out no untoward results were produced. It was frequently a successful substitute for operative interference. The accessories were easily purchased and were of nominal cost.

Dr. Willy Meyer of New York said that he had been interested in this method ever since 1893, when Bier first published his report. In 1894, he had shown before the orthopedic section of the Academy of Medicine cases of tuberculous joint disease cured by means of artificial hyperemia. One of the observations leading up to Bier's method was made long ago by a number of clinicians, including Rokitansky, namely, that patients suffering from stenosis of the mitral valve did not get tuberculosis, or else showed healed lesions of this disease. The hyperemia treated was first applied by means of hot water bags, and then by means of the Esmarch bandage. There was as yet no perfect English equivalent for the German expression "Stauungshyperämie." It might be termed obstructive hyperemia, but at no time was there to be a

stasis in the part. There was to be a continuous flow of blood. Unfortunately, there was as yet no means by which this method could be applied to the hip. Possibly, tuberculous disease of the hip could be reached by placing the entire lower extremity in hyperemia. The elastic garter around the neck was effective in producing hyperemia of the head. The suction flask was a potent means of producing hyperemia, so was that of the hot-air chamber, which was, however, an arterial hyperemia. Bier's treatment was not a panacea for all ills; it did not cure every case; it was only an addition to the therapeutic armamentarium. It was incumbent on every physician to become familiar with this method, for it ramified into every branch of medicine and surgery. It was used successfully in cases of tuberculous joint cases, in mastoiditis, in carbunculosis and furunculosis, in mastitis, felon, and osteomyelitis. In furuncle and carbuncle, the treatment required time, but was successful in limiting the size of the resulting scar. The speaker cited the case of a carbuncle on the back of the neck of a young lady, treated for forty-five minutes each day, for eight days, by means of the suction cup. This treatment usually either prevented suppuration, or else caused the production of a very small core. In mastitis, a treatment extending over six or seven weeks was successful in saving the appearance and function of the breast. Bier's treatment had four cardinal points: it was painless in application, it reduced pain, saved function and prevented scars. Where the physician was busy and had not the time nor assistance necessary to carry out Bier's treatment, it was better to stick to the old treatment. Bier's treatment required time. Wherever there was pus, this had to be evacuated. The speaker detailed the following cases, successfully treated: Acute phlegmon of hand, a large abscess of the inguinal region, which was first evacuated by means of a small incision and expression of the pus, and dacryocystitis. In rheumatism, the elastic bandage was successful in 50 per cent. of the cases. In gonorrheal rheumatism, the application of the bandage diminished pain in every instance. If this was the only successful instance of the application of Bier's treatment, the latter had certainly earned an important place in therapeutics. In acute cases of mastoiditis, the sooner the hyperemia treatment was applied the better. When the mastoid just began to be tender, the application of the simple elastic band about the neck was frequently effective. This treatment was also of value as a prophylaxis in cases of operative wounds of the surgeon's hands. There were very few hospitals in which Bier's treatment could be successfully carried out, owing to the lack of assistants. He prophesied that it would not be long ere the stepchild of medicine would become the favorite.

Physical Diagnosis of Cardiac Diseases.—Dr. C. F. Wainwright of Manhattan read this paper. There were three fundamental points in the physical diagnosis of the heart. First, it was necessary to acquire as much knowledge of the heart as possible by means of inspection and palpation. Second, it was necessary to study the normal heart. Third, it was necessary to study the heart murmurs, the laws of their conduction, and the areas of their maximum intensity. The observation of the heart had been grossly neglected by medical practitioners. There was no valvular lesion that was not associated with physical changes in one or more of the cavities of the heart. For instance, in mitral stenosis there was enlargement of the right ventricle. There were four pathological lesions that led to enlargement of the left ventricle; they were: exophthalmic goiter, arteriosclerosis, mitral insufficiency, and aortic stenosis. The first sound of the heart was caused by the systole of the ventricle, the impact of the heart against the chest wall, and the closure of the auriculoventricular valves, and the second sound was caused by the closure of the semilunar valves. There was no disease of the heart that was not associated with changes in these heart sounds. In the child, the pulmonic second sound was louder than the aortic; in middle life, both of these sounds were of equal intensity, while in old age the aortic sound was the louder. In the later stages of typhoid fever and in other diseases, the first sound resembled the second. The valvular part predominated, owing to the weakening of the cardiac muscle. In mitral stenosis the sound lost its muscular element. Moreover, the apex did not come into contact with the chest wall. The murmurs that were heard loudest at the apex were those caused by mitral stenosis, mitral regurgitation, dynamic murmurs, and the cardiorespiratory murmur. The murmur of mitral stenosis was not transmitted. The dynamic murmur was inconstant. A murmur that exactly resembled that of mitral insufficiency was frequently produced by hysteria or chorea. It varied in its character and would occasionally disappear entirely. Intraventricular murmurs were caused by ruptured cords or by aneurysms of the wall of the heart. These murmurs were not associated with impairment of the functional activity of the heart, nor with changes in the pulse. The cardiorespiratory, dynamic, and intraventricular murmurs were sometimes heard loudest at the base. These cardiac diseases that were frequently overlooked were lesions affecting the aortic valve and the aorta. The aortic stenotic and the intraarterial murmurs were more frequently confused than the murmurs produced by any other heart lesion. One means of distinguishing between the two murmurs was that lesions of the aorta did not compromise the left ventricle, while those of the valves did.

Philadelphia Neurological Society.

At a stated meeting, January 27, Dr. Weiss, by invitation, reported "A Case of Lateral Ankle Clonus." The condition, which has been but rarely described, was observed in a patient of Dr. Spiller's at the Philadelphia Hospital, presenting symptoms of spastic paralysis. Dr. Alfred Gordon described briefly "A Case of Unilateral Ascending Paralysis." Dr. M. D. Bloomfield presented a communication dealing with "The Fraenkel Treatment of Locomotor Ataxia," and he demonstrated an illustrative case. He dwelt on the necessity of careful attention to detail in the reeducation of coordinated movements in the tabetic patient. A noteworthy symptom is an absence of the sense of fatigue, so that for this reason, as well as on account of the liabilitity to unforeseen accident, the treatment should always be carried out under the supervision of a medical man. Dr. W. G. Spiller presented "A Patient with Acquired Bilateral Spasticity and Athetoid Movements." The patient was a boy about 12 years old and the condition had first made its appearance at about the age of 4. It was progressive in development and incapacitated the patient for ordinary activity. The disorder was believed to be due to a degeneration or dystrophy of the lateral columns of the cord. Dr. Spiller also reported "A Case of Encephalitis with Symptoms of Cerebellar Tumor." The specimen exhibited, in addition to other lesions, hemorrhages into the dentate nucleus. Drs. D. J. McCarthy and Milton K. Meyers presented specimens from "A Case of Cerebrospinal Syphilis." Dr. A R. Allen read a paper entitled "The Symptom-complex of Transverse Lesion of the Spinal Cord and Its Relation to Structural Changes Therein." He pointed out the difficulty in determining from the symptoms the degree of injury inflicted upon the spinal cord as a result of destructive lesions and the corresponding difficulty in forming a prognosis and defining the limits of treatment.

At a stated meeting, held February 24, Dr. Alfred Reginald Allen demonstrated "A Case of Paralysis of Associated Upward Movement of the Eyeballs." The patient was a man, about 55 years old, with a history of syphilis, whose right eye moved outward and slightly upward, in attempts to rotate the eyeballs upward. The

right eye did not pass the median line when rotated inward alone, but this movement was completed when carried out in association with outward rotation of the left eye. All other movements of the eyes, singly and in association, were properly carried out. It was thought that the disturbance was due to a lesion destructive of fibers of communication between the oculomotor nucleus on the left and the nucleus of Dartschewitsch on the right. Dr. W. W. HAWKE reported, "A Case of Tabes Dorsalis with Psychosis." The patient had originally presented symptoms of locomotor ataxia with the later developments of characteristic manifestation of paretic dementia, with expansive delusions, but subsequently the symptoms assumed a manic-depressive character. Dr. W. E. CADWALADER exhibited "A Case of Aphasia." The patient was a man, about 60 years old, with slight remains of a previous right hemiplegia and preservation of ability to speak, but with an inability to recognize words and preserved ability to recognize most letters and almost all figures. General intelligence appeared to be unimpaired. Dr. T. H. WEISENBURG exhibited "A Case of Bilateral Involvement of the Cochlear and Vestibular Branches of the Eighth Nerve." The patient was a young man who had first iritis on one side and then on the other, and subsequently tinnitus followed by deafness in one ear after the other. There was also marked vertigo and staggering. Dr. T. A. WILLIAMS of Washington, D. C., read by invitation a paper, entitled "The Pathogenesis of Tabes." He dwelt particularly upon the part played by meningitis in the causation of sclerosis of the posterior columns of the spinal cord through the intermediation of the involvement of the radicular nerves.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

January, 1908.

ANATOMY.

1. Describe the bony pelvis, and state what bounds the cavity of the true pelvis above.
2. How is Poupart's ligament formed? What purpose does it serve?
3. Name the muscles of the abdomen, and give the origin, insertion, and action of any one of them.
4. What structures pass through the foramen magnum?
5. Give the relative position, from without inward, of the structures contained in Scarpa's triangle.
6. Give the origin, course, distribution, and function of the second pair of cranial nerves.
7. Name and bound the ventricles of the brain.
8. Describe the pleural membrane and give its relations.
9. Describe the male urethra.
10. What structures are inclosed within the broad ligaments of the uterus?

BACTERIOLOGY.

1. Describe the two most common pyogenic bacteria, and name the bacteria found in erysipelas, cellulitis, and pyemia.
2. What bacteria are liable to be mistaken for the tubercle bacillus, and how may this error be avoided?
3. Describe ptomains, and name three sources of ptomain poisoning.
4. Give a detailed description of Widal's test in typhoid fever.
5. Write twenty lines upon serum therapy and name diseases in which it has been successfully employed.

PHYSIOLOGY.

1. How are cells reproduced?
2. What are the functions of epithelium?
3. How is cartilage nourished?
4. What are the differences between arterial and venous blood?
5. What physiological process takes place in the capillaries?
6. Give the function of the epiglottis?
7. What are enzymes?
8. How would digestion be affected were the ductus communis choledochus obstructed?
9. Give the physiology of urine excretion.
10. What are the functions of the brain membranes?

HYGIENE.

1. Name the impurities in water that may cause diarrhea.
2. What hygienic precautions should be taken in treating a case of tuberculosis?
3. Give the best method of frying meat and fish, and the reason for your opinion.
4. Tell how to make a beef tea that will be nutritious.
5. Mention and describe the diseases of animals that are communicable to man, and state the means that should be employed for the prevention of these diseases in man.

PRACTICE.

1. Discuss the prophylactic treatment of typhoid fever.
2. Mention the different types of diphtheria and give treatment.
3. Give prognosis in pulmonary tuberculosis.
4. What is the symptomatology of leprosy?
5. How would you treat a case of gonorrheal arthritis?
6. What course may gallstones pursue?
7. Write a short article on Addison's Disease.
8. Name the valvular heart lesions in the order of their frequency of occurrence.
9. How would you manage a case of diabetes mellitus?
10. What may vertigo indicate?

PATHOLOGY.

1. Describe the blood picture in pernicious anemia.
2. What are the microscopical findings in locomotor ataxia?
3. Compare the kidneys microscopically in chronic parenchymatous and chronic interstitial nephritis.
4. Give the morbid anatomy of diphtheria.
5. What are the pathological changes occurring in diabetes mellitus?

SURGERY.

1. How is suppuration developed?
2. Give causes, symptoms, and treatment of osteomyelitis.
3. Name the varieties of ulcer.
4. Name the varieties and general symptoms of fracture.
5. How would you reduce a dislocation of the hip?
6. Give the indications for tracheotomy and how performed.
7. Give symptoms of vesical calculus.
8. Give symptoms and treatment of synovitis.
9. Give causes, symptoms, and treatment of phlebitis.
10. Describe in detail an operation for hemorrhoids.

LEGAL MEDICINE.

1. Give a medical definition of insanity.
2. What is atalectasis? Its effect on the newborn?
3. Of what use is medical examination in life insurance?
4. What constitutes rape? Give medical evidence.
5. Give medical evidence that a child was born at term.

CHEMISTRY.

1. Define elementary and compound matter.
2. What do groups of atoms represent? What is their chemical notation termed?
3. What are normal, acid, basic, and double salts? When one molecule each of hydrogen and chlorine unite, what is formed?
4. State composition, formation and properties of ammonia. How are nitrates formed in nature?
5. What are the properties of urea? Why do urates form deposits in joints and cartilages?

MATERIA MEDICA AND THERAPEUTICS.

1. Give preparations, alkaloids, and physiological action of nux vomica.
2. In what diseases would you prescribe arsenic? Name three preparations of same with dose of each.
3. Name a drug useful as a vasodilator and vasoconstrictor. Give indications for same.
4. Give the dose of apormorphia—give the therapeutic uses for same.
5. Write an ℞ for the following: Lithemia, dysuria, chorea.
6. Mention the incompatibles of digitalis. When, in your opinion, is digitalis contraindicated?
7. Name three preparations of the following drugs and indications for their use; glycyrrhiza, cinchona, camphora.
8. Give child (1 year) and adult dose of acetanilid, morphine, hyoscin.
9. For what conditions would you prescribe the following: Cantharides, capsicum, belladonna, strophanthus?
10. What are the therapeutic uses of the mineral acids?

OBSTETRICS.

1. (*a*) Name the internal generative organ in the female. (*b*) Give brief description of each, and (*c*) functions of each.

2. (*a*) Describe the phenomena of menstruation. (*b*) State the changes that occur in the uterus during menstruation.

3. (*a*) Describe the fetal circulation. (*b*) What changes occur at birth?

4. Give (*a*) probable and (*b*) certain signs of pregnancy. (*c*) Give Hegar's sign and method of eliciting it.

5. (*a*) State three of the most common conditions that might be mistaken for pregnancy. (*b*) Give differential diagnosis.

6. Give (*a*) etiology, (*b*) symptoms, (*c*) treatment of albuminuria of pregnancy.

7. Give (*a*) principal causes of post-partum hemorrhage and (*b*) treatment.

8. (*a*) What conditions justify the induction of premature labor? (*b*) How should it be performed?

9. (*a*) Give symptoms of puerperal fever. (*b*) How would you guard against it, and (*c*) how treat it if it does occur?

10. Give (*a*) diagnosis of a breech presentation, and (*b*) management.

GYNECOLOGY.

1. Give (*a*) causes and (*b*) treatment of pruritus vulvæ.

2. Give (*a*) etiology, (*b*) symptoms, and (*c*) treatment of acute cystitis.

3. Give (*a*) etiology, (*b*) symptoms, and (*c*) treatment of prolapse of the uterus.

4. (*a*) Name the most common causes of sterility in woman and (*b*) state what can be done to overcome them.

5. (*a*) Give differential diagnosis between early pregnancy and a small fibroid tumor. (*b*) How would you replace a retroverted uterus?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

January, 1908.

ANATOMY.

2. Poupart's ligament is formed by the lower border of the aponeurosis of the external oblique muscle; it extends from the anterior superior spine of the ilium to the spine of the pubes.

4. The structures which pass through the foramen magnum are: the medulla and its membranes, vertebral arteries, spinal accessory nerves, anterior and posterior spinal arteries, and the occipito-axial ligament.

5. In Scarpa's triangle the following structures are found, from without inward: external cutaneous nerve, anterior crural nerve, femoral artery, femoral vein.

7. The *Lateral ventricles* of the brain are bounded: *Above*, by the corpus callosum. *Below*, by the caudate nucleus of the corpus striatum, the tænia semicircularis, part of the optic thalamus, choroid plexus, and fimbriated edge of the fornix. *Internally*, by the septum lucidum.

The *third ventricle* is bounded: *Above*, by the fornix, and velum interpositum. *Below*, by the lamina cinerea, tuber cinereum, infundibulum, corpora albicantia, and posterior perforated space. *In front*, by the anterior commissure, and the anterior pillars of the fornix. *Behind*, by the posterior commissure, the iter a tertio ad quartum ventriculum. *Laterally*, by the optic thalami and the peduncles of the pineal gland.

The *fourth ventricle* is bounded: *Above*, by the valve of Vieussens and the cerebellum. *Below*, by the pons and medulla. *Laterally*, by the superior peduncles of the cerebellum, restiform bodies.

The *fifth ventricle* is between the two layers of the septum lucidum, and is therefore between the two lateral ventricles. It is covered over by the corpus callosum.

10. The broad ligaments of the uterus contain the following structures: The Fallopian tubes, the round ligament, the ovary and ligament, the parovarium, loose connective tissue, blood-vessels, and nerves.

BACTERIOLOGY.

1. Two most common pyogenic bacteria:

(1) *Staphylococcus pyogenes albus.* It is a saprophyte; small round-celled with a diameter of about one mikron; clusters in groups like a bunch of grapes; it is facultative anaërobic; it is nonmotile, and has no flagella.

(2) *Staphylococcus pyogenes aureus.* It is very much like the above, only it forms a golden yellow pigment, whereas the *Staphylococcus pyogenes albus* does not.

In *Erysipelas* may be found the Streptococcus erysipelatis, or streptococcus pyogenes.

In *Cellulitis* may be found the staphylococcus pyogenes aureus, citreus, and albus, the streptococcus pyogenes, pneumococcus, gonococcus, bacillus ærogenes capsulatus, bacillus maligni œdematis.

In *Pyemia* may be found the streptococcus pyogenes, staphylococcus pyogenes aureus, pneumococcus, bacillus pyocyaneus, bacillus coli communis, bacillus typhosus, bacillus tetragenus.

2. The bacteria liable to be mistaken for the tubercle bacillus are: the bacillus of leprosy, the bacillus of the smegma, and Lustgarten's bacillus. "The differential diagnosis between these four organisms depends upon the following reactions: When stained by the carbol-fuchsin method, commonly employed in staining the tubercle bacillus, the Lustgarten's bacillus becomes almost instantly decolorized by treatment with mineral acids, particularly sulphuric acid; whereas the smegma bacillus resists such treatment for a much longer time, and the lepra and tubercle bacillus for a still longer time. On the other hand, if decolorization is practised with alcohol instead of acids, the smegma bacillus is the first to lose color. The bacillus tuberculosis and the bacillus of leprosy are both very retentive of their color, even after treatment with acids and alcohol. If, then, we treat the preparation, stained with carbol-fuchsin, with sulphuric acid, Lustgarten's bacillus becomes almost at once decolorized. If it is not immediately decolorized, heat with alcohol; if it is then decolorized, it is the smegma bacillus. If it is still not decolorized, it is either the leprosy or the tubercle bacillus." (From Park's *Pathogenic Bacteria.*)

3. Ptomains are basic, nitrogenous organic substances produced by bacteria. "Owing to the wide variations in the chemical constitution of the ptomains, they possess no characters by which they can be distinguished as a class. Some are strongly alkaline and basic, others only feebly so. Some are liquid, oily and volatile, others fixed and crystalline. Some are very prone to oxidation, and are active reducing agents, others are quite stable. For the same reason, no analytical method is possible by which vegetable alkaloids and ptomains can be separated from each other *en masse*, nor are any reactions known to which all ptomains respond while vegetable alkaloids do not, or the reverse." (Witthaus' *Manual of Chemistry.*)

Three sources of ptomain poisoning: Canned meats, ice-cream, and decomposing fish.

4. Widal's test in typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transporetd for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

5. "*Serum therapy* depends upon the fundamental fact that a group of body cells—for example, those of the central nervous system—have a way of rising to the emergency when compelled to defend themselves against a group of foreign cells (*e.g.* tetanus bacilli) and of producing in excess substances antagonistic to such foreign cells or to their products. Such an antagonism is known as immunity. To be immune against a given cell is to possess the power of poisoning or dissolving that cell. This is known as antibacterial immunity. When the body is attacked, not by cell groups but by cellular products, such as toxins, another type of immunity is produced by virtue of which the blood of the immunized individual is able to neutralize and render inert the toxin molecules." (*Reference Handbook of the Medical Sciences.*)

Diseases in which it has been successfully employed are: Diphtheria, tetanus, snake-bites, and rabies.

PHYSIOLOGY.

2. The *functions of epithelium* are: (1) Protection, (2) secretion, (3) motion (ciliary), (4) special sensation, (5) absorption.

3. Cartilage has no blood-vessels, but is nourished from perichrondrium, from synovial membrane, and from bone.

4. *Arterial blood* is bright red in color, contains more oxygen, less carbon dioxide, more water, and is slightly warmer.

Venous blood is purple in color, contains less oxygen, more carbon dioxide, less water, and is slightly cooler (except in the hepatic vein).

6. The *function of the epiglottis*, is: (1) To prevent food and drink entering the larynx; (2) to modify the voice.

7. Enzymes are unorganized ferments which are the result of the activity of special cells of the animal body.

8. If the ductus communis choledochus were obstructed: there would be an increase in fermentation and putrefaction, an impairment of the emulsification of fats, an increase in peristalsis, and perhaps diarrhea.

10. The *function of the dura* is protection: It forms the internal periosteum of the skull, it forms three partitions for the support of the parts of the brain, it forms sinuses or venous channels for the return of the blood from the brain, and it forms sheaths for the nerves as they leave the skull. The function of the *arachnoid* is lymph supply; of the *pia*, blood supply and nutrition.

HYGIENE.

1. The impurities in water that may cause diarrhea, are: Suspended mineral matters, suspended animal (fecal) and vegetable matters, fetid gases, and an excess of dissolved nitrogenous organic matter.

2. Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woollen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water." (Thompson's *Practical Medicine.*)

4. The following is Bartholow's formula for making beef-tea: A pound of lean beef should be freed from fat, tendon, cartilage, bone, and vessels; it must be chopped up fine, and put in a pint of cold water to digest for two hours. It should simmer on the range or stove for three hours, but the temperature should not exceed 160° Fahr. The water lost by evaporation should be made up by the addition of cold water, so that a pint of beef-tea should represent one pound of beef. It should be strained, the beef being carefully expressed.

5. "Among the most common of the diseases and parasites of animals, which are communicable to man, are: (1) Glanders, a disease of the genus *Equus*, generally fatal when contracted by man; (2) anthrax, a disease of horses, cattle, sheep, and swine, appearing in man either as malignant pustule or as internal anthrax, and often fatal; (3) tuberculosis, a disease common in cattle and swine, but also occurring in horses, sheep, goats, dogs, poultry, cage birds, and menagerie animals; (4) rabies, a disease of the genus *Canis*, communicable to all warm-blooded animals and to man; (5) epizootic aphtha, commonly known as foot-and-mouth disease, a very infectious malady of cattle, sometimes communicated to the consumers of the milk of diseased cattle; (6) *Cysticercus bovis*, found in cattle, is the larval form of the tapeworm of man known as *Tænia saginata;* (7) *Cysticercus cellulosæ*, found in swine, is the larval form of the tapeworm of man known as *Tænia solium;* (8) the *Trichina spiralis*, a common parasite of swine, may develop in man and sometimes produces fatal results; (9) the *Echinococcus* found in the lungs, liver, and other organs of the meat-producing animals is the cystic phase of the *Tænia echinococcus* of the dog.

"It is evident that the most satisfactory way of protecting man from this source of danger is to eradicate these diseases and parasites so far as possible from the domesticated animals. As complete eradication cannot be accomplished for many years and in some cases not at all, there must be constant efforts for repression and control. People must be made familiar with the dangers; too close association with animals should be avoided; the inspection of meat and of dairy cows should be universal; swine flesh should be well cooked; hides, wool, and hair, often infected with the anthrax bacillus, should be handled with suitable precautions; biological products used for the prevention or cure of human diseases should be surrounded with every safeguard to avoid contamination." (*Reference Handbook of the Medical Sciences.*)

PRACTICE.

1. Typhoid fever is preventible. When the municipal authorities do not consider it their duty to supply pure water, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food; flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

3. *Prognosis in pulmonary tuberculosis.* The duration of the disease is variable, but averages about two to two and a half years. According to Osler, "the following may be considered favorable circumstances in the prognosis of pulmonary tuberculosis: A good family history, previous good health, a strong digestion, a suitable environment, and an insidious onset, without high fever, and without extensive pneumonic consolidation. Cases beginning with pleurisy seem to run a more protracted and more favorable course. Repeated attacks of hemoptysis are unfavorable."

8. The most frequent valvular lesion of the heart is mitral regurgitation; then follow mitral stenosis, aortic regurgitation, and aortic stenosis, but the order of these varies according to different writers; tricuspid regurgitation is next; and the least frequent are tricuspid stenosis, pulmonary regurgitation, and pulmonary stenosis, but not necessarily in this order.

10. Vertigo may indicate: Neurasthenia, congestion, or anemia of the brain, eyestrain, disease of the internal ear, meningitis, tumor of cerebrum or cerebellum, gout, indigestion, heart disease, arteriosclerosis, autointoxication. It may also be caused by certain drugs.

PATHOLOGY.

1. In *pernicious anemia* the blood would show: (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes *may be* diminished.

2. In *locomotor ataxia*, the posterior columns of the spinal cord are gray and shrunken and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

3. In *chronic parenchymatous nephritis*, "both degenerative and proliferative changes are seen. The tubular epithelium is always more or less affected, showing signs of cloudy swelling, fatty degeneration, desquamation, and disintegration, most marked in the convoluted tubules, but also present in the loops and collecting tubules. The distribution of these changes is usually patchy, giving rise to mottling of the cortex. The lumina of the tubes may be dilated, and contain granular and fatty matters, and hyaline casts, the latter formed by coagulation of exudation in the tubules. The glomeruli may occasionally appear normal, but there is almost always some swelling and hyaline degeneration, together with some proliferation and desquamation, of the epithelium, so that they become highly cellular. Occasionally the glomerular changes may be more marked than the tubular; fatty degeneration of the glomerular and capsular epithelium may be prominent, or there may be swelling, proliferation, and desquamation of the epithelium, or both these changes may be combined. The glomerular vessels may be compressed, their endothelium degenerate, and they may become obstructed by leucocytes or by hyaline thrombi, and finally obliterated. Interstitial changes, though present, are not conspicuous, and consist of edema, and scattered foci of round-celled infiltration about the glomeruli and veins. Sometimes hemorrhages are evident in some of the glomeruli and the corresponding tubules. Lardaceous infiltration frequently accompanies parenchymatous nephritis."

In *chronic interstitial nephritis*, "the lesions are principally seen in the cortex; at first patches of cellular in-

filtration appear, then the intertubular connective tissue becomes increased and fibrous, with destruction of glomeruli and the corresponding tubules. The glomerular epithelium becomes swollen and desquamates. Bowman's capsules may be much thickened by concentrically arranged layers of nucleated fibrous tissue, and the Malpighian bodies in places may be converted into nodules of fibrous tissue, in others into cysts. The corresponding tubules undergo atrophy with disintegration of their epithelium; here and there multiplication, with convolution of the tubules, may be present, suggesting an adenomatous formation. There is everywhere an increase of the stroma, in the cortex and pyramids, between the tubules, and around the glomeruli and vessels, with pronounced round-celled infiltration or well formed fibrous tissue, in which calcification may occur. The vessel walls are thickened, chiefly owing to an endarteritis. Lardaceous infiltration may accompany the interstitial nephritis." (Hewlett's *Pathology.*)

SURGERY.

1. *Suppuration* is a special form of inflammation, in which the exudate is unusually prolific in cells, and in which pus is found. The cause of suppuration is the invasion of the tissues by pus-producing bacteria, when the said tissues are in a state of lowered vitality or are not capable of withstanding and disposing of the bacteria and their products.

4. Fractures are variously classified:

(a) Simple, compound, and complicated.

(b) Complete (transverse, oblique, spiral, longitudinal) and incomplete (fissured, greenstick).

(c) Single and multiple.

(d) Comminuted, impacted, etc.

(e) Intra- and extraarticular; intra- and extracapsular.

The *general symptoms of fracture,* are: History of injury, disability, pain, swelling, deformity, abnormal mobility, and crepitus.

7. The *symptoms of vesical calculus,* are: Increased frequency of micturition; pain at end of urination, chiefly felt at the end of the penis or in the neck of the bladder; the urine may contain pus, mucus, or blood; a "click" can be obtained by using a searcher or sound; examination by the cystoscope may reveal the presence of the stone.

LEGAL MEDICINE.

1. Insanity is defined, in Allbutt's System of Medicine, as "such a disorder or disease of the nervous system as prevents the individual from reacting normally as a member of the society to which by birth and education he belongs."

2. *Atelectasis* is the condition in which some of the air-vesicles of the lung are not inflated, and hence there is imperfect expansion of the lung.

Its effect on the new-born is to cause pallor or cyanosis, rapid and shallow respirations, and feeble cry; the infant is weak.

3. The use of medical examination in life insurance is to enable the company to form an estimate of the general health of the applicant and so to gauge his expectation of life.

4. *Rape* is carnal knowledge of a female by a man, unlawfully, forcibly, and without her free consent.

The *medical evidence* is based on: (1) Marks of violence about the woman's genital organs; (2) wounds, bruises, or other marks of injury on the woman or on the accused; (3) blood stains and seminal stains on the person or clothing of either party; and (4) the presence of any venereal disease on either party.

CHEMISTRY.

1. *Elementary matter* is such matter as cannot by any known means be split up into other kinds of matter.

Compound matter is such matter as is made up of two or more kinds of elementary matter chemically united, in definite proportions.

2. Groups of atoms represent molecules.

The chemical notation of an atom is termed a symbol; of a molecule, a formula.

3. *Normal salts* are those in which all the hydrogen of the acid has been replaced.

Acid salts are those in which only a part of the hydrogen of the acid has been replaced.

Basic salts are compounds of normal salts with the hydroxide, or oxide, of a metal.

Double salts are those which are formed by the substitution of different elements or radicals for two or more atoms of the replaceable hydrogen of the acid.

When one molecule each of hydrogen and chlorine unite, two molecules of hydrochloric acid are formed.

4. Ammonia. *Composition,* three atoms of hydrogen chemically united with one atom of nitrogen: NH_3.

Formation, by heating a solution of ammonium hydroxide: $(NH_4)HO = H_2O + NH_3$.

Properties, a colorless gas with a pungent irritating odor, and a caustic taste; it is very soluble in water, also in alcohol; it combines readily with water; it also combines with acids to form ammonium salts, this union is direct, and hydrogen is not separated.

5. *Properties of urea:* It is a crystalline solid, soluble in water, colorless, odorless, with a slightly bitter taste; it is neutral in reaction, but basic in character; dilute aqueous solutions are not decomposed by boiling, but by prolonged boiling urea is hydrolyzed to ammonia and carbon dioxide; urea forms compounds with acids and also with certain salts and oxides.

Why urates form deposits in joints and cartilages *is not known.*

MATERIA MEDICA AND THERAPEUTICS.

1. Nux Vomica. *Preparations:* Extract, fluid extract, and tincture of nux vomica; strychnine, sulphate, and nitrate of strychnine.

Alkaloids: Strychnine and brucine.

Physical action: It excites the digestive secretions, increases the appetite, increases peristalsis, and improves the digestion; it is a vasoconstrictor, it raises blood pressure, and is a cardiac stimulant; it is also a respiratory stimulant; hearing and sight are rendered more acute.

2. Arsenic could be *prescribed in:* Malaria, gastric ulcer, and cancer, dyspepsia, anemia, chlorosis, chorea, neurasthenia, rheumatism, chronic skin diseases, lupus.

Three preparations, with dose: Liquor potassii arsenitis, ♏vij; Arseni trioxidum, gr. 1/30; Liquor sodii arsenatis, ♏v.

3. A Vasodilator—Amyl nitrite. Indicated in: Angina pectoris, cardiac dyspnea, epilepsy, asthma, tetanus, and migraine.

A Vasonconstrictor—Adrenalin. Indicated in: Hemorrhages, hay fever, bronchial asthma, Addison's disease.

4. *Dose of apomorphia:* gr. 1/10 of the hydrochloride.

Therapeutic uses: As an emetic, an expectorant (in acute and chronic bronchitis, catarrhal pneumonia, pulmonary tuberculosis).

8.

	DOSE FOR CHILD OF ONE YEAR.	DOSE FOR ADULT.
Acetanilid	Should not be given.	gr. iv.
Morphine	gr. 1/100.	gr. 1/4.
Hyoscin	Should not be given.	gr. 1/128.

OBSTETRICS.

4. (*a*) *Probable signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

(*b*) *Certain signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical souffle.

(*c*) *Hegar's sign* consists in a thinning and softening of a segment of the body of the uterus immediately above the cervix.

It is elicited by pressing the finger of one hand into the vagina, high up behind the cervix, and with the fingers of the other hand making pressure externally above and behind the symphysis pubis.

5. (*a*) Three of the most common conditions that may be mistaken for pregnancy are: (1) Ovarian cystoma; (2) ascites; (3) uterine fibroid.

(*b*) *Differential diagnosis.—Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Ovarian cystoma: Absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

Ascites: Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides; the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregu-

lar, being, as a rule, slow, and sometimes extending over years.

GYNECOLOGY.

1. (*a*) Pruritus vulvæ may be *caused by*: Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin, or idiopathic.

(*b*) *Treatment* consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1:2,000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

2. ACUTE CYSTITIS.—(*a*) *Etiology*: Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold.

(*b*) *Symptoms*: Frequent urination, with tenesmus and a burning sensation in the urethra, later on pain in the bladder, hematuria, and the urine contains pus and epithelial cells. Chills, rapid pulse, fever, and headache may also be present.

(*c*) *Treatment* includes: Rest, administration of plenty of cold water or milk, diuretics, bland and mild food, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

4. (*a*) *The most common causes of sterility in woman*, are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix.

(*b*) *Treatment* consists in removing the cause, if possible; curettage has been reocmmended; in the presence of developmental errors, little or nothing can be done; atresia of cervix can be treated by dilatation; if the uterus is misplaced it must be replaced.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery		
Arizona*	Ancil Martin, Phoenix	Phoenix	July	6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	August	4
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July	7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July	14
Delaware	J. H. Wilson, Dover	Dover	June	16
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	April	14
Florida*	J. D. Fernandez, Jacksonville	Ocala	April	13
Georgia	E. R. Anthony, Griffin	Atlanta	May	—
Idaho	W. F. Howard, Pocatello	Boise	October	6
Illinois	J. A. Egan, Springfield	Chicago	April	15
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May	26
Iowa	Louis A. Thomas, Des Moines	Des Moines	June	—
Kansas	D. P. Cook, Clay Center	Kansas City	June	9
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April	28
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May	21

CONSTRUCTIVE SURGERY AFTER EXTENSIVE GUNSHOT WOUND OF ABDOMEN.*

BY W. M. POLK, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL SURGERY, DEPARTMENT OF GYNECOLOGY CORNELL UNIVERSITY MEDICAL COLLEGE.

ON December 9, 1904, the wound I will describe was inflicted by the accidental discharge of both barrels of a shotgun, the muzzle being directly against the body, with three layers of clothing intervening—a hunting jacket, the usual shirt, and underclothing. The sportsman was approaching a covey of birds with both barrels cocked and prepared to fire, when he trod upon a wet, slanting depression in the ground, slipped, lost balance, and fell, with the above result.

The contents of the two barrels struck the abdomen at and above the anterior superior spinous process of the left ilium and came out at and above the iliosacral joint, tearing away all the soft tissue from the crest of the ilium and the crest itself, above a line drawn from a point one inch back of the anterior superior process, around the outside of the bone to the upper limit of the sacroiliac joint. The joint was not entered, but the outer half of the transverse processes of the two lower vertebræ were torn off. Many pieces of detached and semi-detached bone were scattered throughout the entire field of the deeper parts of the wound. The only portion of the crest that escaped fracture was that in the immediate region of the anterior superior process, but between it and the inferior process this space was stripped of all tissue but the periosteum. The upper limit of the wound ran in the main parallel to the lower, diverging somewhat upward as it ran back to end at about the vertical center line of the erector spinæ muscle of the corresponding side. The width of wound with the patient resting on the right side was about two and three-quarter inches in front, gradually increasing to about four and one-half behind. About midway the wound was bridged by a piece of skin tissue averaging two and one-half inches in width; its inner surface was cleanly swept of all other tissue. This bridge served to prevent retraction of the skin layer, but all tissue beneath had shrunk away, so that the subcutaneous dimensions of the wound were even greater than the surface measurements above given indicate. The internal limits of the wound were difficult to determine, but Dr. Royster, of Raleigh, N. C., who first saw the case, was able to discover that the peritoneal cavity had been entered, exposing the sigmoid flexure, the lower pole of the left kidney, and the anterior end of the floating rib. The exposed surface of the sigmoid colon extended from the anterior edge of the wound as far back as the kidney; its peritoneal coat had been blown or burnt off, showing the muscular fibers. At the time of the accident it was uncertain whether this intestine had been perforated, but within a day or two some leakage of gas showed that one or two of the shot had entered it. As already said, the top of the ilium was blown away, fragments of it being found deep down beneath the iliacus muscle almost at the linear terminalis in the neighborhood of the iliosacral junction. On the outer aspect of the ilium the pieces were scattered among the remnants of the upper glutei muscles. All these muscles appeared to have been detached largely through the explosive effects of the discharge. Of course the destruction of the bone and muscles was due to the combined action of the shot and powder. The lumbar muscle was practically destroyed, and all of that portion of the abdominal muscles proper which lay to the rear of a line vertical to the anterior superior spinous process. Owing to the mangled state of the tissues hemorrhage was comparatively slight, so that, although the patient lay unaided upon the ground for some time, he subsequently, supported by a companion, drove a mile to a near-by dwelling house. The admirable judgment displayed by Dr. Royster had much to do with the subsequent freedom from sepsis which the patient experienced. He very properly declined to disturb the surfaces by attempts to determine the exact depth of the injury which had been inflicted, especially as there were no evidences of dangerous hemorrhage. The burning which the tissues had undergone practically sterilized the whole surface. This, of course, Dr. Royster recognized, and he therefore merely cut away and removed the many exposed shreds of bone, muscle, and skin, added a superficial sterile dressing, and saw that the patient was made quiet and received proper nursing. About two weeks after injury he was transferred about one thousand miles to New York. A mild septic fever began to show itself, and it was evident there was a gradual increase of fecal leakage from a minute opening at about the center of the exposed sigmoid. It was also evident that the patient must be anesthetized and the several sinuses, which led to pieces of dead bone, cleared out. This had been deferred because the wound was doing well, with no more elevation of temperature than so large an exposed surface would give. Under ether a number of pieces of bone varying from three-quarters of an inch square to less, were removed, one piece being found beneath the psoas, practically at the edge of the inner pelvis. The periosteum having necrosed over the anterior superior spinous process, that portion of the crest was removed, and the jagged ends extending all the way round to the lumbar spine were cut away. An attempt at the same time was made to close the opening in the intestine, but the injury done to the muscular coat as well as the peritoneum left practically little but mucous membrane at the point of perforation to be dealt with, the attempt resulted in a fail-

*Read before the meeting of the Practitioners' Society of New York, March 6, 1908.

ure. After this, barring an attack of mild delirium, which seemed to be a sequence of shock, and possibly the infection, the general conditions were satisfactory. At the end of four months the opening in the intestine had so far enlarged itself that all of

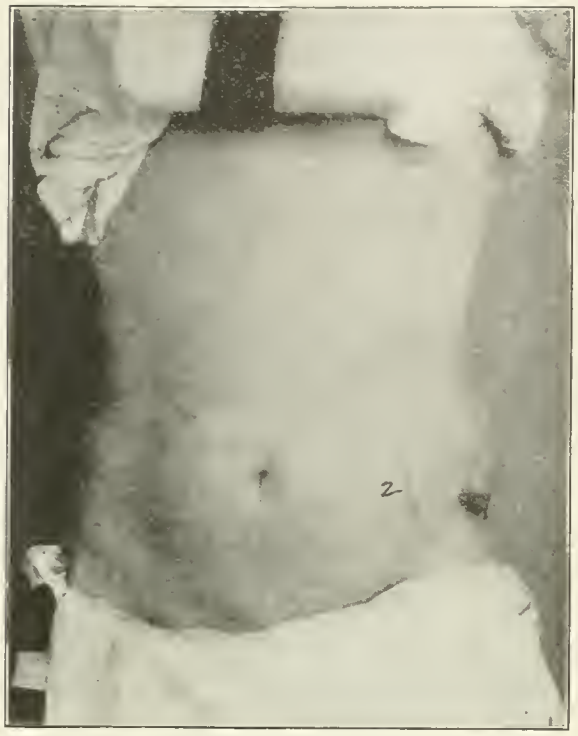

Fig. 1.—Two years after injury. Front view. 1. Original injury. 2. Site of abdominal opening for anastomosis.

the bowel contents were discharged through the side. The hole in the abdominal wall was diminishing under persistent strapping with plaster. It was now necessary to determine how much of an operation should be undertaken for the relief of the conditions existing. The major difficulty lay not in closing the intestine, but in securing the proper covering for it, and it was evident that if the operation was deferred for a few months longer a sufficient amount of contraction would take place around the wound to lessen this difficulty materially. In order, however, to make sure that the function of the rectum was maintained, I concluded that an anastomosis between the transverse colon and sigmoid had best be made. Dr. Bull saw the case with me and coincided in this view. This question of the atony of the rectum in consequence of disuse, is still in dispute, some claiming that even though several years may elapse it can resume its functions without difficulty, but it was preferred to avoid the contingency if possible. I therefore made the anastomosis with a large Murphy button, entering the abdomen just outside the left rectus muscle, Dr. Bull kindly lending his aid. The operation was easily done, as the sigmoid colon was found to have a good mesentery. The transverse colon was readily brought into apposition with it, the points of union being the upper surface of the sigmoid, and the lower surface of the transverse colon beneath the great omentum. The closure of the traumatic opening in the sigmoid at that time might have been undertaken, but not an attempt to furnish a protective covering. I had therefore concluded, as above stated, to perform an anastomosis as a temporary expedient, leaving the sigmoid wound as well as that in the abdominal wall to be handled later. In three months the fecal discharge through the opening in the sigmoid was about equivalent to what it was prior to the anastomosis. As the opening of anastomosis was readily accessible to the finger introduced at the sigmoid wound, I made a cautious attempt at dilatation, but feared a tear in the attachment, so desisted (it was not more than one-third inch in diameter, with rigid edge). From time to time fecal matter found its way into the rectum, and with the aid of enemas this region was kept active. The patient's health continued to improve steadily, putting on fat moderately. The dimensions of the larger outside wound had been materially diminished by persistently drawing together by adhesive plaster applied in the main perpendicularly. The posterior third of the opening was in this manner closed and gradually the edges of the opening in the gut and that in the wall approached till they coincided, the one filling the other.

One year after the sigmoid injury I devised and executed the following operation:

The wisdom of delay was by that time clearly established. The general wound had cicatrized and contracted about the sigmoid to such an extent that the opening in the wall and that in the gut coincided. This opening measured three and three-quarter inches horizontally by two and one-half vertically. At all times there was much prolapse of the everted colon, chiefly the descending, the mass not infrequently reaching the size of a man's fist.

The first step in this operation was the separation of the intestine from the surrounding wall and then closing it. After being separated, the opening in the gut was spontaneously lessened somewhat, but still the large oval opening narrowing at its extremities

Fig. 2.—Front lateral view. 1. Site of traumatism. 2. Abdomen incision for anastomosis.

and widening at the middle involved so much of the circumference of the gut, particularly at its widest part, as to raise a doubt as to the proper line of procedure. This doubt was still further increased by the necessity for removing the thickened cicatri-

cized edges in case we decided to close this opening, rather than resect. There was ample room for resection had it not been for the attachment at the point of anastomosis. This reduced somewhat the amount of intestine below the traumatic opening at disposal for such an operation. I concluded to close this opening. Closing it longitudinally would have been unwise, as the gut would have been too much narrowed at the central portions of the opening. I therefore closed it transversely, making thus an elbow in the gut, widening it at that point. Through-and-through primary sutures were used with the usual peritoneal surface sutures all interrupted. The next question was to provide adequate covering. Fortunately the omentum was abundant and its displacement to the left dependent upon the anastomosis made it easy to draw it over the entire opening. This had expanded after the intestine had been cut out, so that its measurement was now increased from one-half to three-quarters of an inch, the general outline remaining oval as before. The first step was to provide a parietal peritoneal covering for the restored sigmoid; to this end the omentum was drawn over the intestine without tension, and stitched to the under edge of the abdominal opening throughout its entire circumference. This afforded ample parietal peritoneal covering. It was out of the question to find either fascia or muscle for our purpose, so we were compelled to rest satisfied with a supercovering of fat and skin. Vertical incisions were therefore made through the skin and fat at either extremity of the opening, the longest arm being through the gluteal region, the skin with the fat was then dissected from its under attachment beginning at edges of wound, and drawn together over the omentum. The major portion of the flap was taken from the gluteal region. A small piece of rubber tissue drain

Fig. 3.—Rear view. 1. Scar line. 2. Lower limit of hernial protrusion which overrides the upper edge of the ilium.

was inserted at the anterior angle of the wound and dressings applied. The patient was then returned to bed. Care was taken by the frequent passage of the rectal tube to keep down the accumulation of gas in the lower bowel. A through-and-through movement was obtained by a mild catharsis on the second day, and from that time on the progress of the case was uneventful. In all of this work I was much indebted to my associates, Dr. Hamlin and Dr. Brown.

Fig. 4. Front view. Support as habitually worn.

Now, two years after the operation, I will show the patient. He gives you an idea of the extent of the injury and the result of the efforts that have been made to overcome it. He is able to perform the duties of his daily life, walking four and five miles a day for recreation, and with slight encouragement would take up field shooting again. The action of his bowels, with the entire digestion, is excellent; in fact, his health could not be better.

The chief points of interest in the case are the wide extent of the injury, the nature of the tissues involved, the four separate operations undertaken before cure was established, and the cure, as evinced by the present condition of the patient's health, viz., his ability to walk and attend to the duties of life, the excellent state of the bowels in spite of the lack of proper support over the field of injury, and the efficiency of the artificial support which he employs to keep the abdominal contents in place.

As to the operations, the first, by Dr. Royster, consisted of the careful inspection of the wound, the removal from it of the shreds of clothing and of mangled tissue, the recognition of the fact that the force of the explosion and the heat accompanying it had glued the sigmoid in position so that, although there was a wide opening into the abdominal cavity, this temporary attachment of the upper edge of the wound to the sigmoid was so firm as to prevent the protrusion of any other intestine. The recognition also by Dr. Royster of the unwisdom of disturbing this attachment, and also his recognition of the aseptic condition of the wound caused by the burning it had received from the explosion.

The points in the second operation related to the necessity for removing the anterior portion of the

crest of the ilium, which had become denuded of periosteum—the depth at which fragments of bone were found, notably on the inner face of the ilium, beneath the iliacus muscle, where, as before stated, one fragment was removed from the brim of the true pelvis lying there beneath the psoas muscle and separated but a short distance from the common iliac vessels. In this connection attention is drawn to the efficiency of the prolonged use of strapping with zinc plaster so as to narrow the wound as much as possible, and the result which was obtained in securing the juncture of the skin over the posterior third of the wound, thereby diminishing the gap subsequently to be closed by operation.

The third operation relates to the anstomosis between the transverse colon and the sigmoid. The point selected was the under surface of the transverse colon between the mesocolon and omentum at the junction of the middle and left third of that viscus. The point of the sigmoid selected was that which could most easily be brought in apposition with the colon. The anastomosis being at the under side of the transverse colon, the omentum was spread out in its usual apron-like fashion between the intestines and the abdominal wall. The point of entrance to abdominal cavity was about two inches to the inner side of the traumatic opening, about at the outer edge of the left rectus muscle.

The problems in the fourth operation were, first, the proper method of closing the intestinal opening; second, the furnishing of a parietal peritoneum against which the intestine could rest, in that way minimizing the chances of adhesion and lessening the chances of subsequent perforation from ulcerative processes in the exposed intestinal area. It was realized that if the sigmoid were not provided with such a covering, it would become adherent throughout to a large extent and that that area would always be exposed to possible perforation from any ulceration of the mucous membrane which might subsequently occur; third, the finding of an external covering for what must be a large hernia, and, fourth, the devising of some plan by which its extension and enlargement in the future could be controlled. The manner in which these several problems have been met has been here described and the result is now before you.

7 East Thirty-sixth Street.

A PHENOMENAL AORTIC ANEURYSM.*

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

The occurrence of an abdominal aortic aneurysm of falsely sacculated and dissecting type, measuring 6 x 9 x 11 inches, containing 6½ quarts of fluid blood and clots (3,500 c.c.), causing marked displacement of the kidneys, and erosion of five vertebræ, is so unusual a phenomenon as to merit permanent record. The case is of further interest from the fact that until within three weeks of his death, the patient was able to walk about. He became mentally deranged, however, and his "friends," to get rid of him, had him arrested upon a bogus charge of attempted suicide from gas poisoning, so that he was finally brought to the Presbyterian Hospital, accompanied by a burly policeman, as an illustration of the practical working of the absurd State antisuicide law, which makes attempted self-destruction a penal offence, and under which there has never yet been a conviction!

Fig. 1.—Abdominal aneurysm, extending from the diaphragm to the prominence of the sacrum, measuring 6 x 9 x 11 inches, and containing 3,500 c.c. of clots and blood.

The patient was an Italian day laborer, 39 years of age. He had contracted syphilis when 21 years old, for which he had been treated. With this exception he had had no other illness but malaria, until

*A paper read before the Practitioners' Society, March 6, 1908.

four years prior to his death, when he had much general abdominal pain accompanied by melina, which occurred from time to time for several months. He recovered, and remained well for a year, when, two years and a half before he came under observation, he was again attacked by severe abdominal pains which chiefly occupied the lower right side of the abdomen and radiated down the right thigh, being often worse at night. He suffered also from constipation and frequent micturition. These symptoms continued with varying severity until within six months of the patient's admission to the hospital when the pains in the abdomen and right thigh became severe and frequent. They were made markedly worse upon standing, when the abdomen became distended and tense, hard and tender, but upon sitting or lying down, the patient was relieved. He lost much weight and became anemic.

FIG. 2.—Erosion of the eleventh and twelfth dorsal and the first, second and third lumbar vertebræ, caused by an abdominal aneurysm.

Upon admission to the hospital the man appeared emaciated and pale and suffered great pain upon attempting to fully extend the right leg. Blood examination showed a hemoglobin percentage of 35, a red cell count of 2,600,000 and a polynucleosis of 87 per cent. The heart appeared normal in size, but the rhythm was infantile and a faint systolic bruit was apparent over the apex and base. The arteries were moderately thickened and the pulse dicrotic, of poor quality. In the chest were signs of a moderate bronchopneumonia with fluid in the left pleural cavity. Behind both liver and spleen were large strongly pulsating masses which caused considerable bulging of the lower ribs posteriorly. Upon the right side especially, the expansile pulsation was visible through an arc of fully half an inch, and there was a sensation of fluctuation, but without definite bruit at that region. Anteriorly tumor masses of harder feel extended into the groin on both sides, and on the right a hard mass the size of an egg was distinctly felt lying superficially a couple of inches above Poupart's ligament. This mass, and a similar one less distinctly felt upon the left, I mistook for new growths, but they proved to be the dislocated kidneys imbedded in a mass of connective tissue so dense that at autopsy they had to be dissected out before their real nature became apparent.

The right side of the abdomen was very prominent anteriorly, but the only site where a bruit was distinctly audible was over a limited area to the left of the umbilicus. This fact must have been due to the number of large clots which filled the tumor.

It was difficult to believe that so large a mass, bulging out the abdomen over both flanks and behind both liver and spleen could be a single aneurysm, and at one time there seemed reason to suspect that it was a multiple angiosarcoma of gigantic proportions. This belief was encouraged by the variations in density of the tumors, pulsating in parts, elsewhere hard and nodular, and by the patient's condition of emaciation and anemia. The fluctuating mass to the outside of and behind the liver, suggested the presence of an abscess with transmitted pulsation, a belief supported by the blood examination which showed a high polynucleosis. I therefore suggested to the house physician to put in an aspirating needle at this point, but to use a small one. The needle must have passed into a clot, for it yielded no result, beyond a few drops of blood. The subsequent rapid increase in size of the mass and increase in intensity of pulsation left little doubt that it must be an aneurysm, but even at autopsy the mass was so obscured by dense connective tissue and distorted muscles and viscera, that it was not until it was laid open that its nature became certain. The irregular density and shape of the mass, as felt through the abdominal wall, was explained by the variations in thickness of the aneurysmal sac and the unexpected position of the imbedded kidneys.

After eight days in hospital, the patient died from edema of the lungs and brain. The autopsy, performed by Dr. Meakins of the pathological department, is summarized as follows:

Autopsy.—The liver, which weighed only 1,000 grams, was thin and flattened against the anterior abdominal wall; it occupied a normal position, and showed fatty degeneration. The spleen weighed 200 grams, and was bound in the normal position by adhesions. Both kidneys lay below the umbilicus, the right being a couple of inches above Poupart's ligament, and both were in contact with the abdominal wall, imbedded in a mass of connective tissue; they weighed 50 grams each, and the capsules were adherent. To remove the aneurysm entire the psoas and iliacus muscles had to be removed upon both sides, leaving only the skin of the posterior abdominal wall. The aneurysm occupied the entire posterior part of the abdomen, extending from the diaphragm to the lower border of the sacral prominence, in the median line, and reaching down on either side as far as Poupart's ligament. On removing the large laminated clots which filled most of the cavity, the wall of the aneurysm was found composed of the intima, the other arterial coats being indistinguishable excepting over a very small area. The aneurysm appeared to have originated from the posterior wall of the abdominal aorta, not from any of its branches. Five vertebræ were eroded, viz., the eleventh and twelfth dorsal, first,

second, and third lumbar. The first lumbar vertebra was so deeply eroded that the meninges were exposed, and a groove three-fourths of an inch in depth occupied the anterior part of its body.

The heart was normal in size, firm, and showed some increase in fibrous tissue; the myocardium was firm and the coronary arteries were clear; the mitral and aortic cusps were somewhat thickened, and atheromatous plaques involved the base of the thoracic aorta. At the root of the thoracic aorta a small fusiform aneurysm (3½-6 cm. in diameter), was discovered. Both pleuræ were adherent, and in the left pleural cavity were about 300 c.c. of clear serum. Bronchopneumonia was present.

The patient's emaciation may have been due to pressure upon the pancreas or ductus choledochus or liver, but neither sugar nor bile were discovered in the urine. The only suffering of which he complained while in hospital was from pain in the right leg which he kept in semiflexion. He was too ill to justify an exhaustive study of the reflexes or condition of the spine before death.

Aneurysms of this type and size are exceedingly rare, and have sometimes been mistaken for angiosarcoma, or parasitic tumors (actinomycosis, hydatids, etc.), pulsating abscesses or cysts. Sansom, of London, writing of this topic, states: "It is surprising how large an aneurysm and how considerable a displacement of organs may be undetected when the sac is close to the vertebral column and does not bulge forward."* He also refers to the paroxysmal and nocturnal type of pain existing when there is erosion of the vertebræ, a phenomenon noted in the case above reported.

In a statistical study of 10,360 autopsies made in Jena, Ernst Müller† found 69 cases of aneurysm which involved some portion of the aorta, but only 6 of these sprang from the abdominal aorta, one in a female, 5 in males. Thus a ratio of scarcely more than 3 per cent. were abdominal in this series. Among 468 cases of aneurysm at St. Bartholomew's Hospital 23 were of the abdominal aorta (approximately 5 per cent.). At the Presbyterian Hospital, New York, during the past 25 years the clinical diagnosis of aneurysm has been made 158 times. Among these cases 108 were aneurysms of the aorta, including 21 of the abdominal aorta. As the earlier records of the hospital, however, are somewhat defective, this large proportion of abdominal aneurysms, so at variance with experience elsewhere, must be attributed, in the cases unconfirmed by autopsy, to a too frequent inclusion of simple pulsating aorta. In Bellevue Hospital during the past five years there have been 82 cases of aneurysm of the aorta, including only three of the abdominal division, among 81,338 patients treated on the medical service alone.

In the case above described it is reasonable to suppose from the history, that the lesion began in the abdominal aorta about two and a half years prior to death and developed rapidly during the last six months of the man's life. Considering the phenomenal size of the mass and the compression and displacements to which it gave rise, it is astonishing that the patient presented so few subjective symptoms.

†"Zur Statistik der Aneurysmen" (Thesis).

34 East Thirty-first Street.

Abnormal Appetite.—From Silesia comes the report of an operation on a young girl who had swallowed an enormous number of nails, pins, and needles. The entire mass of foreign material is said to have weighed three pounds.

A CASE OF RECURRENT JAUNDICE; DEATH IN THIRD ATTACK FROM CARCINOMA OF PANCREAS.*

By GEORGE L. PEABODY, M.D.,

NEW YORK.

The patient whose duodenum and adjacent viscera I had intended to show you this evening was a woman, thirty-five years of age, of sedentary occupation, whose habits were good and who presented nothing significant in her family history, nor in her previous personal history. I have been compelled to abandon the demonstration of the organs concerned in her death, because it has been found necessary to destroy the lesion of chief interest, namely a small annular carcinoma beneath the mucous membrane of the duodenum in order to ascertain its origin.

Two years before she came under my care in the New York Hospital she had her first attack of jaundice, preceded by a chill, nausea, and vomiting. Nausea and vomiting lasted several days before jaundice began; and the nausea continued for two weeks after onset of jaundice. This latter was entirely painless, and lasted three months. During all this time her stools were clay-colored. Then she gradually recovered, the jaundice passed away, and she considered herself well.

Eight months later she had a similar attack. Like the first, it was entirely painless, and both preceded and accompanied by nausea and vomiting. The jaundice in this attack lasted between five and six months, and she became very weak.

Seven months after this recovery, and six weeks before she entered the New York Hospital she had the third and fatal attack.

This attack was distinguished from the previous ones by the occasional but irregular occurrence of chills, after the jaundice had become very pronounced.

Nausea and vomiting occurred frequently, and anorexia was persistent.

There was never any vomiting of blood in any of the attacks. This attack was as completely painless as were the others, but towards the end of her life her enlarged liver was very tender on palpation. She suffered much from thirst. She had lost twenty-two pounds in the last attack, and about forty-six pounds since the beginning of her illness, two years previously.

Her nose bled twice, but not persistently. She had an insignificant cough, without expectoration. Her chief complaints were of jaundice and weakness.

On careful questioning she adhered to her statement that these attacks had always been preceded by four or five days of nausea and vomiting.

Inspection revealed a condition of very deep jaundice. There was the well-known greenish black hue to the deeply yellow skin that goes with icterus gravis.

The liver seemed enlarged in all directions, and extended three fingers' breadth below the free margin of the ribs. The gall-bladder could not be made out, nor could any abnormal masses be distinguished by careful palpation of the abdomen. The spleen was enlarged and very readily palpable. Its consistence was very firm.

The heart sounds and pulse were feeble, 116 to the minute, respiration was 24, and temperature 103.2°. She was somnolent, and indifferent in her manner, and very profoundly prostrated.

*Read at the meeting of the Practitioners' Society, March 6, 1908.

Her blood was repeatedly examined, and it showed generally a slight reduction in the number of leucocytes: Polymorphonuclears were usually about 93 per cent., red cells, 3,840,000.

She took almost no food, was frequently nauseated, rarely vomited, became progressively weaker, more indifferent, somnolent, and died, comatose eleven days after entering the hospital.

Until the last three days of her life, when her temperature was normal, she had fever which was occasionally intermittent, usually continuous, and never quite reached 104°.

Her stools, which were always clay-colored, contained much free fat and fat crystals, no parasites or ova, and, for the most part, no blood visible either to the eye or through the microscope, although blood could always be recognized in them chemically. On the day before she died she passed per anum an elongated blood-clot about three inches long and rather more than half an inch in diameter. Toward the close of her life her pulse fell to 90, 84, 80.

Her urine could not be measured, because it was passed either with her stools or involuntarily; but it seemed to be scanty in amount.

It was examined very frequently. It was always acid, varied in specific gravity from 1010 to 1018, always contained a heavy precipitate of albumin, many granular casts (both finely and coarsely granular) abundance of bile, and never any blood or sugar.

It seemed to me that we had to do with a case of obstructive jaundice apparently catarrhal in its onset, without biliary calculi, and so much graver than catarrhal jaundice usually is as to suggest some other subsidiary or contributory factor which I was unable to make out, and could only suspect to be a carcinoma.

The autopsy was made the day after death by Drs. Elser and Symmers, the pathologists of the hospital.

They found a stricture of the common bile duct and the duct of Wirsung, for they did not enter the duodenum by a common opening. The latter entered the duodenum just below the former. The stricture was caused by a small annular carcinoma of scirrhus variety which completely surrounded the papilla of Vater, just beneath the mucous membrane and deeply invading the muscular structure of the gut.

The diameter of this ring of cancerous tissue was less than an inch and its thickness in all directions less than a third of an inch. It lay in close proximity to the head of the pancreas: but its origin in the pancreas could be proved only by examining repeated sections cut completely through the wall of the ring. At first sight it did not seem to be connected with the pancreas at all.

Through the papilla of Vater could be passed only a very small probe.

Among the organs which showed changes of importance came, first, the liver. It was markedly enlarged, of olive green color, of denser consistency than normal, its markings on cut surface unusually distinct.

Under the microscope it showed the usual effects of bile-stasis, and early cirrhosis, with proliferation of small bile-ducts as is usual in this condition.

The gall-bladder was markedly dilated and filled with a viscid fluid, having the appearance of a bile-tinged serum. The mucosa appeared atrophied, with indistinct markings. The cystic duct was dilated to about the size of a lead pencil. The common and hepatic ducts were dilated so as to be about three times the diameter of the dilated cystic duct. They contained a fluid similar to that found in the gall-bladder. The gall-bladder lay completely concealed beneath the liver, a fact which accounted for its not being palpable, although it was greatly increased in size.

The pancreas was nodular throughout, of very unusually firm consistence. The duct of Wirsung was markedly dilated except at its point of entry into the duodenum, just below the common duct, where it was markedly constricted by the small tumor-mass already described. There was no evidence of either gallstones or pancreatic stones. Microscopic examination of the pancreas showed a condition of pressure-atrophy of the gland cells and a very extensive interlobular cirrhosis. The islands of Langerhans showed no structural changes, and no carcinoma was found except that which formed the stricture.

The kidneys were both the same in appearance. They were enlarged. Capsules were thin, and stripped with unusual readiness. Surface was smooth, unusually moist, dark greenish-red in color, and opaque.

Cut section showed the entire organs markedly edematous. The cortex was thickened—markings were fairly distinct in some places, but indistinct in others. Consistence seemed slightly increased.

Under the microscope the kidneys showed the lesions of acute parenchymatous nephritis, a high grade of edema of the interstitial tissue, acute glomerulitis.

The spleen was enlarged, and showed firm fibrous adhesions over posterior aspect and upper pole of the organ. Tension of its capsule was increased. Cut section was fairly smooth, and dark red in color. Malpighian bodies and stroma were fairly distinct.

The stomach was small and atrophic, and covered with a thin mucus.

Intestines.—The lowermost portion of the ilium and the upper portion of the large intestine showed a high grade of congestion of the mucosa. The descending colon contained a number of altered blood-clots.

Mesenteric and retroperitoneal lymph nodes were swollen and edematous, but revealed no evidences of a new growth. No metastases were found anywhere.

Cultures taken from the following fluids and organs at autopsy showed pure cultures of *Bacillus capsulatus mucosus*, namely: Blood from median cephalic vein, gall-bladder, kidneys, liver, spleen.

I have sections to show you of the carcinoma, pancreas, liver, kidneys, and spleen, which show readily the microscopic lesions which I have described.

The case is a somewhat unusual one and did not admit of a positive diagnosis during life, although from the extreme gravity of it one could not help thinking of a carcinomatous stricture. There would have been little question of this diagnosis in my mind had it not been for the two previous attacks of jaundice, each of them protracted through months, and each very prostrating.

It was quite evident that the patient was suffering from obstructive jaundice, and that the obstruction was not due to cholelithiasis. It also seemed likely that duodenitis was a contributing factor; but the severity, fever, rapid pulse, and above all the emaciation, suggested the presence of a neoplasm occluding the common duct by pressure.

Mayo and Cammidge in their recent book on the "Pancreas" make the following statement: "Whenever in a patient at or past middle age, jaundice comes on painlessly and becomes absolute, at the

same time that the gall-bladder gradually enlarges so as to form a perceptible tumor, and the patient rapidly loses flesh and strength, a diagnosis of cancer of the head of the pancreas will probably be correct."

It is not likely that this carcinoma had to do with the two previous attacks of jaundice, for although of slow growth its growth is steadily progressive. It is not likely to have been intermittent in its causation of jaundice, and it probably did not exist longer than a year. It seems to me probable that the two earlier attacks of jaundice were of catarrhal etiology.

BRIGHT'S DISEASE AND ITS TREATMENT.

By OTTO LERCH, A.M., M.D., Ph D.,

NEW ORLEANS.

PROFESSOR OF MEDICAL DIAGNOSIS, NEW ORLEANS POLYCLINIC POST-GRADUATE DEPARTMENT OF TULANE UNIVERSITY OF LOUISIANA.

In 1827 Richard Bright published the statement that albuminuria and dropsy are symptoms of kidney disease, and ever since that time the term Bright's disease has been applied to diffuse nephritis. By diffuse nephritis is understood a constitutional disease involving both kidneys and mostly both tissues —parenchymatous and interstitial. We speak of a parenchymatous nephritis remembering that in a large number of cases the interstitium is involved as well, and interstial nephritis without parenchymatous involvement does not exist. Some authors do not wish to have the name Bright's disease retained; however the term is so generally accepted by the practitioner that it would be difficult to eliminate it from our nomenclature, even if that were advisable.

The most prominent symptoms are still edema and albuminuria, hardly ever absent and always occasionally present. The face, especially the eyelids, and the shins are most frequently the seat of the edema of Bright's disease, not rarely allowing a differential diagnosis from heart disease, the edema of which commences in the feet and ankles and from the diseases of the liver and peritoneum, which are marked by ascites. The etiology, the course of the disease, the examination of the urine and of every organ allow generally a correct diagnosis of the special form.

Bright's disease is a constitutional disease. In every instance an intoxication of some kind is the cause—the toxins of the microorganisms of the acute and chronic infectious diseases—the toxins of the diseases of metabolism, gout and diabetes, and certain poisons ingested. The toxic substances are carried by the blood to the kidneys, there giving rise to the disease. This characteristic etiological feature makes it at once clear why next to the kidneys the heart, vessels, and liver have to suffer, though not an organ in the body escapes injury—the perfect condition of all depends on pure blood—a differentiation except in typical advanced cases is not always easy to make. The acute parenchymatous form may gradually pass into the chronic form and this into the sclerotic kidney. The exacerbations of chronic parenchymatous and interstitial nephritis may be mistaken for the acute disease, and the congested kidney of circulatory disturbances resembles acute nephritis.

Fat droplets in epithelial cells coming from the kidneys, and fatty casts in the sediment of the urine indicate chronic parenchymatous changes; and absence of sediment and large quantities of urine voided speak in favor of an interstitial process. The albuminuria of the infectious fevers is frequently due to cloudy swelling of the kidney epithelium and may be the only symptoms of a chronic process not discovered till years have passed.

The so-called physiological and cyclical albuminurias observed in some individuals at certain times, after eating or exertion, are always to be regarded with suspicion. In these cases the kidneys are locus minoris resistentiæ and these albuminurias have been frequently seen to pass into chronic interstitial nephritis.

Acute nephritis accompanies or follows in the wake of the infectious diseases, though the absorption of toxins produced in chronic diseases of the digestive tract, the ingestion of certain drugs, and exposure and chilling of surface may cause it. All anatomical elements may be involved. The exudation is excessive and glomeruli and tubules are choked with débris. If the process is catarrhal it is curable, and even if croupous complete recovery frequently takes place, not leaving a trace of the serious trouble. If the interstitium is involved the danger that the disease passes into chronicity is great. The patient presents a typical picture. The face is bloated, the color pale, and the general anasarca gives a waxy appearance. The excessive edema is due to the injured vessels and to heart weakness, pronounced if cardiac disease, as is so often the case, complicates the trouble. Every function is interfered with. Dyspnea, complete anorexia, nausea and vomiting, diarrhea, headaches, convulsions, paralysis, epileptic seizures, and amaurosis due to cerebral edema, some or all may be present in such a general intoxication. The urine is diminished in quantity, of dark color, of high specific gravity, contains a large amount of albumin, and the sediment contains casts of every description, usually blood corpuscles and epithelial cells.

According to the severity, the process may last from a few days to months. The kidney is large and heavy, dark red or gray in color, and its capsule easily peels. It is a hemorrhagic or an anemic kidney.

The clinical picture of an acute exacerbation of the chronic and interstitial forms does not differ from that of acute nephritis and the two can be differentiated only by the history and the changes that have been produced in heart and vessels, lungs, liver, and spleen. If acute nephritis passes into the chronic forms, the symptoms become gradually less marked as the storm passes. Edema and albuminuria decrease, the scanty urine changes with copious and frequent urination, the pale face, the puffy eyelids, and the edema of feet and ankles persist. The urine contains albumin, fat, epithelial cells, granular and frequently waxy casts. The kidney is generally large, though it may be of normal size, and in addition to the lesions of nephritis amyloid degeneration is often present. As the process continues the chronic form may pass into the sclerotic kidney, and as a cure is of rare occurrence this is in most instances to be considered a favorable termination.

The symptoms of the amyloid kidney, not always classed as a form of Bright's disease, because it is not due to a process of inflammation, resemble those of the chronic form, yet it is rarely difficult to make a correct diagnosis from the etiology—chronic phthisis, malaria, lues, or an old suppuration somewhere in the body.

The degeneration is not alone present in the kidneys, but always marked in liver and spleen; both organs are enlarged, and when palpated are felt to

be of waxy consistency. The gastrointestinal disturbances are severe, due to the degeneration of their glands. The urine is generally of large quantity, clear, with only a few hyaline and granular casts and a large amount of albumin, though frequent changes in the composition of the urine are observed. Cardiac hypertrophy, retinitis, uremia are rare and may be considered due to a combination of amyloid and indurative nephritis. The kidney may resemble the large white or the contracted kidney; amyloid degeneration is its characteristic feature.

The contracting kidney is by far the most frequent, and the causes that produce it are numerous. Either hard work and exposure or a life of ease and luxury may cause it, as well as mental labor and anxiety, gout, arteriosclerosis and alcoholism, lead intoxication, malaria, lues, and diabetes. As in all other forms of morbus Brightii the toxic substances produced by these various causes are directly at fault. High arterial tension, venous congestion, and interstitial tissue growth with consequent destruction of parenchyma are its main pathological features. It is a very serious disease and a frequent, if not the most frequent, cause of death—not directly, but through intercurrent diseases. Its cause is manifold, its onset is insidious, its progress is slow and steady. It is found in all walks and stations of life, both sexes are subject to it, and there is not a disease that with such steadiness and certainty undermines the general health and lowers the resisting power of the body with so little warning, as does this form of Bright's disease. Not an organ in the body is spared, and changes are wrought daily and hourly, the system adapting itself to these changes as they progress, so that the patient feels only occasional, and in the beginning very slight disturbances of general health, for which he finds ready relief by enforced rest and the drugs dispensed to him. When finally a thorough examination is made, and an advanced stage of the disease is discovered sometimes accidentally, warnings may be disregarded and further valuable time lost, till an apoplexy, a pneumonia, or cardiac failure due to an advanced myocarditis, closes the scene. This peculiar course of the disease is readily understood when we consider life led under normal conditions. Even then toxic substances constantly retained in the blood may cause, in the course of years, thickening of vessel walls and artheromatous degeneration, hypertrophy and myocarditis of the heart, cirrhotic processes in lungs, liver, and kidneys.

The kidney of the aged differs but little from the kidney of interstitial nephritis, and the changes are produced even in normal condition, with comparative rapidity. It has been said that after the age of 40 all kidneys are diseased. That the kidneys should suffer most we understand, if we remember that these organs practically consist of a mass of tubules surrounded by numberless capillaries *constantly* filtering toxins ingested and the waste of metabolism constantly formed.

The most frequent causes of death in interstitial nephritis are the most frequent causes of death of the aged—pneumonia, apoplexy, myocarditis, though of course any trifling cause may break down a worn-out organism. Interstitial nephritis is a premature old age and its intelligent and prophylactic treatment is best adapted to ward off old age.

The causes of the disease explain the insidious onset, the slow and steady progress, the absence of suffering till late, and the pathological features—local irritaion, congestion, round-cell infiltration, formation of interstitial tissue, destruction of tubules, and atrophy of the glomeruli. Even in this advanced stage large areas of normal and hypertrophied tissue may be found in the kidneys.

The interstitial tissue growth is the most prominent feature of the disease and has furnished its most generally applied name, "interstitial nephritis and contracting kidney," due to the common cause, toxic substances in the blood. Endarteritis is rarely absent and changes are produced throughout the vascular system. The heart answers with hypertrophy the demand for more work to overcome peripheral resistance, and with the tense pulse we find associated a lifting apex beat and an accentuated second aortic sound. As time advances the pulse becomes wiry, accompanied frequently by a hypertrophied and dilated heart, degeneration of its muscular tissue progresses, and the distressing symptoms of a failing heart follow, cyanosis, dyspnea, edema, congestion of the viscera, and concentrated urine loaded with sediments. Murmurs are heard over every valve and the patient presents the picture of advanced heart disease.

A healthy arterial system will sustain high blood pressure, but when it becomes diseased, its elasticity will be insufficient and give rise to miliary aneurysm in the cerebral circulation where capillaries which do not anastomose nourish the internal capsule. This is a common symptom in interstitial nephritis and the changes that have taken place in the arteries may be observed in the fundus of the eye, where they often cause retinitis. After the formation of miliary aneurysms in the cerebral circulation even a slight increase of pressure may cause rupture and hemorrhage, and so we see these patients struck by apoplexy after a heavy meal, in the bath tub, at stool, or on their way home from office, or even at work with their usual occupation. Chronic bronchitis, emphysema, and liver cirrhosis are expressions of the common cause that has made the kidney lesion a prominent feature of a constitutional disease. In fact, the disease means chronic inflammatory changes in every organ of the body.

The urine, when the disease is well established, is characteristic. Large quantities are voided and the patient has to rise at night to empty his bladder. The color is pale, the specific gravity low, and it contains but little sediment; generally a few hyaline casts are discovered and chemical tests reveal traces of albumin. It is the one form of Bright's disease in which albumin is not always present, and during the course of which perfectly normal urine may be voided. This is readily explained by the pathogenesis-interstitial tissue growth, encroaching and destroying parenchyma, leaving large areas of functioning kidney tissue intact and hypertrophied.

If the cause is once established the intoxication of the system is constant and its action upon it, like a drop of water that hollows a stone, is hastened by the involutions of advancing years. This is the reason why it is so difficult, and frequently impossible, to make an early diagnosis. Pulse tension, occasional headaches, indigestion, neuralgia, and rheumatic pains are the early symptoms, and as they soon pass with and without treatment, and are often due to minor local disturbances, they may be taken lightly and the disease allowed to pass on till serious changes have taken place. The arterial walls become thickened and the vessels roll under the fingers, the apex beat lifting and the second aortic sound being accentuated. Headaches, gastrointestinal disturbances, neuralgias, and rheumatic pains

are of longer duration, and more difficult to relieve; dizziness, fainting spells, and occasional attacks of asthma occur and the patient notices that he has to void a larger quantity of urine and that he has frequently to rise at night. Even at this stage the urine may be most of the time free from albumin and casts, and is often found normal. And again, years may pass, symptoms coming and going, the disease not being recognized until perhaps an acute exacerbation of the chronic process settles the diagnosis.

The temperature rises to 102°, sometimes 103° and 104°, there is delirium and convulsions and coma may cause death. The urine, usually light greenish in color and of low specific gravity, free from albumin and casts, is now concentrated and contains both. However, as stated before, this is not the most frequent cause of death, but an intercurrent disease; a pneumonia, an apoplexy, or an infectious disease will break down the undermined system.

The kidney of pregnancy, which gives the characteristic symptoms of Bright's disease and may be classed under this head, is caused by pressure upon the renal veins and excess of waste matter in the blood.

The treatment promises much and the gloomy view constantly expressed is wrong and unnecessary. The very name scares the patient and causes such depression that in most cases it is wise to withhold it. Acute nephritis is curable, chronic nephritis may be converted into the interstitial form, and if the etiological factor that causes the contracting kidney is eliminated at a time when the disease is still in its incipiency, there can be no doubt that the progress of the disease can be checked and an apparent cure effected. On the other hand, we must be fully aware that parenchymatous tissue when destroyed cannot be remade once fibrous tissue is formed, and that the disease in its last stages is fatal.

Early symptoms, no matter how light, must be regarded as serious. If the favorable time is allowed to pass, cure becomes more and more impossible, relief of distressing symptoms more and more difficult, and the fatal issue is only a question of time. Statistics are unreliable because the patients are usually carried off by intercurrent diseases; damaged kidneys provide a favorable soil for almost any disease, and death follows, when with these organs sound the patient would pass smoothly through the attack.

The treatment of acute nephritis is first of all preventive. During an infectious disease and after the disease has run its course, the kidneys have to be watched and the urine has to be frequently examined. Pure water, vichy, milk, and buttermilk must be freely administered to flush the kidneys, and drugs that irritate them should be given with the greatest caution.

Absolute rest in bed is the treatment after the disease has been established, no matter how mild the case. There is no drug known that exercises a beneficial influence upon the process. Thorough elimination by skin, bowels, lungs, and kidney, and rest to the organ are the indications. A flushing of the kidneys freeing tubules and glomeruli from débris is desirable. However, the edema present and the state of the circulatory apparatus must guide the administration of the liquids. If the congested and diseased kidneys refuse to eliminate, the liquid will be retained and increase the edema. In such a case its administration must be diminished and thirst quenched by giving crushed ice. Milk is the best diet to begin the treatment, gradually adding crackers, zwieback, some of the green vegetables, and freshly pressed fruit juices, as lemonades.

The tepid bath increases diuresis and effects a flushing of the kidneys. The bowels have to be kept freely open, sulphocarbolate of sodium and of zinc given; if diarrhea is present beta-napthol or other antiseptics may be administered to prevent fermentation. For practical purposes it is sufficient to administer these antiseptics in doses large enough to make the stools odorless or to add bismuth and to continue to increase until this salt is found white in the dejections. If the nephritis is due to chilling of surface, the treatment ought to be commenced with a steam or hot air bath. Severe pain in the region of the kidneys demands hot fomentation or a Priesnitz bandage.

If edema is excessive and does not yield to the hygienic and dietetic treatment, the usual measures have to be taken—saline laxatives to produce watery stools—hot baths, hot packs, and hot air baths (the last can be conveniently administered with the patient in bed) using the simple and well known method with an alcohol lamp and bent tube.

Of the diuretics only those that are not irritating ought to be administered: the tartrates and acetates of sodium and potassium, lemon juice, infusion of juniper berries, infusion of digitalis, and benzoate of sodium.

The hygienic-dietetic treatment, the hydrotherapeutic measures, the saline laxatives, and the diuretics all are useful and sometimes necessary. During an acute attack all food must be withdrawn. Chloroform inhalations and hypodermic injections of morphine to stop spasm; venesection in suitable cases, and hot injections of normal salt solution may be tried—pilocarpine if the lungs are not seriously damaged.

The treatment of the chronic form does not materially differ, though rest and diet must be modified to conform to less vigorous demands.

The treatment of interstitial nephritis must vary according to the stage to which the disease has progressed. Knowing that the outset is insidious and slow and that it takes months and years to establish changes that interfere with normal health, it becomes of the highest importance to make an early diagnosis and not to wait for symptoms that already indicate an advanced state.

The hereditary and personal history furnishing etiological data, a pulse of more than normal tension, the apex beat lifting, the second sound over the aorta accentuated, and a tendency to catarrhs, will in many instances furnish an indication to begin treatment. More than that, in families with a gouty tendency the physician will act wisely in forming the habits of the children to save them from future troubles.

The first indication in all cases is of course to treat the cause, next to regulate the habits of the patient by employing a hygienic regimen. If the disease is not too far advanced these measures will be found sufficient to keep the patient in good health to the end of his natural life. The physician must prescribe them in each individual case, as they must necessarily vary.

There are, however, certain rules that ought to be observed in every instance. There should be a careful selection of clothes for protection against colds to which all nephritics are subject; a non-stimulating diet to lessen blood-pressure and to avoid irritation of the urinary apparatus. That is, the

amount of meat taken must be limited if possible to not more than once a day, and alcohol, spices, condiments, coffe, and strong tea should be avoided.

An out-door life as far as possible should be advised and rest and exercise must be well proportioned.

After the disease has advanced it is often of advantage, especially during acute exacerbations, to prescribe a milk diet for a time in order to procure rest for liver and kidneys. The milk diet, of course, is not curative in this form of Bright's disease. A change of climate is often found beneficial, the climate to be selected according to the idiosyncrasies of the patient.

In the more advanced cases the symptoms as they appear indicate the treatment. The tense pulse and the hypertrophied heart call for relief. The nitrites, nitroglycerin, and the iodides are the most reliable agents to be employed for this purpose.

The drugs must be given for the effect, that is, until the pulse has become soft. By lessening the arterial tension we lighten the heart's labor, counteract its hypertrophy, stimulate elimination, and make our patients comfortable by relieving dyspnea and a train of symptoms due to a serious interference with a proper nutrition of the tissues.

The treatment of uremic symptoms, headaches, rheumatism, neuralgias, gastrointestinal disturbances, convulsions, etc., is: (1) To prevent or limit the production of toxic substances by a carefully chosen diet, in the severer cases an occasional milk or buttermilk diet. (2) To favor elimination by skin, lungs, intestines, kidneys. (3) To burn up toxic substances by well selected exercise in the open air—of course in every case short of fatigue.

Blood-letting in the robust is sometimes very efficient to overcome a crisis. Thirty-two grams of blood contain more toxic matter than 100 litres of perspiration.

A combination of caffeine and sodium benzoate acts well as an eliminant if the kidneys are not impermeable. Cardiac tonics are only indicated if the heart has commenced to fail, the apex beat has become wavy and imperceptible, the pulse frequent, irregular, and thready. Digitalis must be given, if at all, with caution and its action on the heart as well as on the vessels must be remembered. Hydrotherapy furnishes us always with a very valuable adjuvant in the treatment of this affection, and the method is indicated (1) for the care of the skin; (2) for the treatment of chronic uremic conditions; (3) for the treatment of dropsy; (4) for the treatment of acute uremic attacks.

The care of the skin is best attained by ordering a warm bath twice or three times a week, duration one-half hour. The bath is best followed by one or two hours' rest in bed in order to avoid colds. All nephritics are predisposed to colds. The temperature of the bathroom has to be carefully regulated and the cloth used after the bath must be dry and warm. Such a treatment will frequently relieve the symptoms of uremic poison, headache, loss of appetite, indigestion, etc. Sometimes the sweat bath acts better. This is given in moderation by directing the patient to take a bath of a temperature of 40° C. (104° F.) and have him sweat in a dry pack after the bath. Instead, the hot air bath in bed or in the cabinet may be administered. A combination proves sometimes of greater advantage. For instance, first day, warm bath; second day, hot air bath; third day, rest. The hot air bath, like the warm bath, is best followed by rest in bed and not by a cold ablution as is the custom. The main indication for the sweat bath is edema. There can be no doubt that the edemas due to nephritis are favorably influenced by the sweat bath.

Thickening of the blood can be counteracted by directing the patient to drink freely during the bath. Whenever this bath is given the heart must be intact. Winternitz advises the sweat bath of the lower half of the body with an ice bag over the heart. This is the only condition in which cold applications have been advised. The bath ought not to last longer than from five to ten minutes; it is given as an excitant.

To encourage patients to drink large quantities of water with the idea of flushing the kidneys is useless and will do harm. The urine is copious and clear and the circulatory apparatus rarely intact. These patients as well as those suffering from chronic nephritis with edema ought not to be sent to mineral springs.

In conclusion, I again call attention to the necessity of an early recognition of the disease and the beginning of the treatment at an early stage. If this favorable time is allowed to pass, a cure becomes more and more impossible with each succeeding year, with each succeeding month, and relief of harassing symptoms more and more difficult; and after the disease has advanced beyond a certain point all remedies fail, the pulse loses its tension, the heart beats wildly, cerebral symptoms continue, and the patient dies. Far more frequently, however, patients are carried off by intercurrent diseases. This remote cause is hardly ever recorded in our mortality tables and in many instances it may not be recognized. It is on this account that the danger is often overlooked and that the statistics fall short of the truth.

We treat as most serious the first uncertain symptoms of tuberculosis, realizing that if left alone the patient, as a rule, will succumb within a few years. Yet, even certain symptoms of a beginning contracting kidney are neglected. It is true that frequently the end is far off at that time, nevertheless, it will destroy life with just the certainty that consumption does. It seems advisable that we regard the first symptoms with apprehension and commence treatment with all the vigor this insidious, slow, progressive, and most dangerous disease demands.

ELECTROMECHANICAL AND THERMIC REMOVAL OF LOCAL STASIS.*

By WILLIAM BENHAM SNOW, M.D.,

NEW YORK.

The induration associated with every inflammatory process—local stasis—is a beneficent provision of Nature only in so far as it is a safeguard, walling off infection. In all other than cases of inflammation associated with infection, stasis is the obnoxious feature of the process, calling for removal if treatment is to be successful.

The reason in all probability that a truth so patent when once called to the attention of reflecting clinicians, has not been long recognized is that no satisfactory means has been recognized in the past for its effectual removal. Massage, even in most skillful hands, is generally ineffective and so practically is mechanical vibration. The effect of a measure which by external pressure induces the removal of infiltration, is to produce thereby irrita-

*Read at the II. Congrès International de Physiotherapie, at Rome, Italy, October, 1907.

tion and to a degree maceration at the site of the stasis after its removal, and it does not leave the tissues in a tonic, but rather in an irritated condition which induces a relapse. On the other hand a modality which induces intrinsic activity in the structures of the part or region involved, effects the removal of plastic and fluid material without the induction of irritation, and afterwards leaves the tissues in a tonic condition which prevents recurrence of the induration.

In the early stage of inflammation the thermic effects of moist heat or radiant light and heat radiations may be very effective, if the administrations are kept up to the height of toleration for long enough periods—three to six hours. This method is the one *par excellence* in the early stage of superficial streptococcic or staphylococcic infections, because the early softening of the induration which follows permits the larger number of phagocytes present with the hypermia to invade the site of infection and destroy the germs, which are coincidently rendered inert by the action of the heat, or heat and light radiations—an effect opsonic as it were.

Applications of heat at first induce locally intense hyperemia, but when they are prolonged this is followed by profound anemia with contraction of the proximal tissues as of the fingers and arms of the washerwoman, to be followed a considerable time after discontinuance by a return to normal. This is demonstrated by keeping an affected finger in a water bath as hot as can be borne until pain or pressure has ceased, which may require a few hours. A felon or whitlow will invariably promptly disappear if this measure is adopted during the first 36 hours. Similar appropriate applications to suppurative tonsillitis, boils, or carbuncles are effective for the same reasons. In the deeper processes as in mastoiditis, otitis media, and suprapubic congestions, combined radiant light and heat radiations of great intensity, employed for periods of thirty or forty minutes, at least twice daily, maintaining dry or moist surface applications in the intervals, are as a rule effective when instituted early, and beneficial at any stage.

Radiant heat when administered from a source of high candle power, is more penetrating over a large area than local heat applications, as has been demonstrated by passing a thermometer into the female bladder or the penis and making first applications of dry heat and then radiant heat from a high candle power incandescent lamp in the same case. When radiant heat and light are employed the added effects of light increase the inhibitory effect upon pathogenic bacteria.

The electromechanical effects of the static modalities in removing "obnoxious" stasis, as Bier terms it, for the relief of inflammatory processes were first published by the author in a paper on "The Effects of Electrostatic Modalities in the Treatment of Hyperemia and Pain."* In this paper substantially the following observations were made: Pathologically considered, hyperemia arises from circulatory disturbances due to pressure, infection, traumatism, tissue necrosis, obstruction, or paralysis of the muscular coats of the vessels, it may become active or congestive, or exist as a passive hyperemia. "When a strong stimulus acts upon a vascular part" (say Landois and Stirling), "hyperemic redness and swelling occur. Microscopic observation shows that the capillaries and the small vessels are dilated and overfilled with blood corpuscles; simultaneously the velocity of the stream changes; rarely there is a temporary acceleration, more frequently it becomes slower. If the action of the stimulus or irritant be continued, the retardation becomes considerable, the stream moves in jerks, then follows a to-and-fro movement of the blood column—a sign that stagnation has taken place in other vascular areas. At last the blood stream comes completely to a standstill—stasis—and the blood-vessels are plugged with blood corpuscles. Numerous colorless blood corpuscles are found in the stationary blood. Whilst these various processes are taking place, the colorless corpuscles —more rarely the red—pass out of the vessels. Under favorable circumstances the stasis may disappear. The swelling which occurs in the neighborhood of inflamed parts is chiefly due to the exudation of plasma in the surrounding tissues."

If tissue proliferation is not deferred on account of the intensity of the inflammation, regeneration takes place in from eight to twelve hours, when it will be established permanently and without hypertrophy. If, however, the congestion is marked the stasis will persist, when repair may be long deferred.

The processes of regeneration following congestion are often delayed by one or more of the following causes: (1) The exciting cause may still be present. (2) The inflammation may be so intense that the swelling and stasis persist. (3) The lymphatics may from shock or pressure be rendered inactive and slow in removing the products of inflammation. (4) The exuded fibrin and degenerated blood cells may be deposited in the vicinity of structures not well supplied with lymphatics, as so often happens in the joints. (5) The presence of microorganisms which develop characteristic tissue change and degeneration, keep up irritation delaying restoration, and, if not removed, eventually destroy the function of the part. (6) There may be retained necrosed tissue, as dead bone. (7) In diathetic diseases, it does seem that irritants have either accumulated at the site of the inflammatory processes, or are being constantly added and not properly eliminated—defective metabolism. In both types of hyperemia the indications are apparent—removal.

That electricity of great potential, low periodicity, and small quantity removes obstacles to regeneration and promotes normal tissue proliferation by inducing profound contraction, tissue vibration, and cellular activity is demonstrated by clinical experience.

These results are due to the diffuse penetration with the induction of contraction of muscular and yellow elastic tissue at the site of the administration. The writer has demonstrated by personal tests and clinical results that these modalities do have these effects and has failed to derive the same effects from any other source to the same extent as from the static current with which we are able to control the periodicity and amplitude by regulating the spark-gap and speed of the revolving plates. No other interrupter or mechanical device has been constructed in connection with an electrical apparatus to modify all of the qualities of fineness of amplitude, and rate of change of potential, as the regulating spark-gap and speed control of the current output of the static machine; and no other apparatus has nor, we believe, will produce the same quality of diffuse and extensive tissue contraction as the static currents.

*Transactions of the American Electro-Therapeutic Association for 1901. (*Advanced Therapeutics*, March, 1902, page 166.)

That the electrical action of the currents, electrolytic, cataphoric, or electrochemical, are not essentially of value in relieving conditions of stasis, is evident from the fact that the best results are obtained from the static currents that possess those qualities in the least degree.

That there is an additional energizing, stimulating effect upon cell protoplasm derived from these currents which is not induced by vibration and is not alone local, there is abundant proof in the tonic condition of the tissues which hastens normal activities, including regeneration and restoration, when stasis and impaired metabolism are present.

The induction of activity, both local and general, contributes in all inflammatory conditions to the removal of local stasis and the restoration of normal tissue proliferation and regeneration.

Conditions of passive hyperemia associated with edema, as present with organic diseases of the liver, heart, and kidneys, and in cases of varicose veins resulting from thrombosis of the larger vessels of the extremities, offer little or no encouragement to electrostatic treatment. Those cases arising, however, from lost tone of the arterial or venous walls, obstructive functional derangement of some part of the glandular system, or from pressure, as from constipation in the cases of hemorrhoids, or cases of surgical edema following operations or accidents, are successfully treated in all but exceptional cases by the static modalities.

Early treatment greatly enhances the prospect of a prompt restoration to normal; it is the principle *a priori* in all cases. Degeneration and structural alteration preclude the possibility of complete restoration, and when they are found a longer period to induce a condition approaching normal is required.

When a gland, as the liver or pancreas, is the seat of hyperemia, the application of a metal electrode over the organ, and the employment of the static wave current, measured by as long a spark-gap as can be administered without causing too great pain, induces general contraction with successive release of the organ resulting, before degeneration is present, in complete restoration to normal. If hemorrhoids are to be treated employ a proper vacuum electrode with connections and arrangement as for the wave current, and held in position by an *x*-ray tube holder.

In the effects of the static modalities upon acute congestive hyperemia is to be found the greatest triumph of modern electrotherapeutics, early administration insuring prompt restoration in simple inflammation, removing stasis and restoring circulation with restitution.

Therapeutically, the static modalities meet in a most complete and satisfactory manner the essential indications in inflammatory conditions not characterized by the presence of microorganisms, or of some foreign or necrosed substance which cannot be promptly absorbed or forced out through the circulatory channels, when its use must be replaced by or follow the use of surgical intervention, the *x*-ray, radiant light and heat, or high frequency currents—one or more of them.

The modalities of particular value in influencing the conditions of stasis to which they are adapted are the wave and static induced currents, the static brush discharge, sparks, the direct vacuum tube current and spray, which produce in varying degrees the following effects:

(1) By the diffuse, penetrating qualities of the current, contractions are induced and stasis, the disturbing influence to the processes of repair, is removed.

(2) In acute cases, the exudate, which may have accumulated, is promptly absorbed and the tissues are softened so that the swelling may disappear during the first administration.

(3) In chronic cases, fibrin and other organized products of inflammation, which have exuded into the tissues, are gradually eliminated by the wave current when not too deeply situated, or better still by the direct static sparks.

(4) Local circulation is restored and active metabolism induced when the processes of cell proliferation and restitution are undoubtedly accelerated.

(5) When indolent or irritable ulcers or affections associated with the growth of bacteria are present in the skin, the surrounding induration is removed, the surface is stimulated, and superficially the germs are destroyed by the static brush discharge.

(6) Prolonged administrations of the brush discharge or spray produce superficial rubefacient effects.

(7) Pain disappears early if the current has softened the induration, and will not return if administrations are sufficiently frequent to prevent relapse and control the congestion and pressure.

(8) Throughout the economy, by the passage of the current from electrode to the surface of the insulated patient, functional activity is increased, associated with the restoration, if dormant, of the nutritive and secretory processes.

Since the first presentation of the effects of the mechanical action of the static modalities in the treatment of inflammatory stasis I have made numerous contributions bearing upon the same topic.*

In each of these contributions it has been shown that other forms of electrical energy or other modalities do not so effectively remove obstructive stasis as the static currents which exert without causing irritation the most diffuse, intrinsic, and energetic mechanical tissue contraction.

I have in accord with these principles during recent years evolved methods of treating inflammatory congested conditions, a few of the most important of which follow:

Prostatitis and seminal vesiculitis, as treated by me are among the most significant and important of my discoveries. While treating with the static wave current a case of intrapelvic neuritis with a metal electrode passed into the rectum, the writer and other physicians present observed that an enlarged prostate gland was very much reduced in size, softened, and rendered less sensitive by the administration. This observation led to the employment of the method the following year in a very severe case of prostatitis. The conditions under which this patient, 63 years of age, suffered, were extreme. The prostate was greatly hypertrophied and very sensitive to pressure. The patient was suffering from a very distressing dysuria and frequent micturition and was in a dejected and melancholy state of mind.

The method consists in passing into the rectum and in contact with the two lobes of the gland, a

*Electrostatic Modes of Application and Uses of the *x*-Ray, pages 72 to 76. Currents of High Potential of High and Other Frequencies, pages 104, 112, 122, and 134, and in the paper presented at the I. Congrès de Physiothérapie, held at Liége, on "The Mechanical Effects of Electricity in Therapeutics." *Archives of the Roentgen Ray*, March, 1906, page 216 and others.

straight metal electrode 15 centimeters in length, provided with an insulated handle, bulbous at the end and narrowing to the handle, the patient lying on his side upon a suitable reclining chair with his back towards the machine. The electrode, placed in contact, is held in position by the hand of the patient. A wire is connected from the handle of the electrode to the positive side of the static machine, the patient being insulated, and the negative pole of the machine is grounded by a direct metallic connection to the earth. The discharging rods of the machine are placed so that the balls are near together. After starting the machine the balls are gradually separated until the length of the spark-gap is such that the patient complains of discomfort, due to the contraction induced in the tender viscus. At this time the spark-gap may not be more than one inch in length, but before the end of the séance of twenty minutes, it will be gradually increased to three inches. The relief following this administration in the first case so treated was surprising. The sense of weight in the perineum was diminished and the patient felt greatly relieved. The same application was given on the four subsequent days, after which administrations were made every second day for three weeks, when he was discharged. Since this treatment that patient has had no relapse, has not been compelled to rise nights, and has suffered absolutely no discomfort from the prostate; he is now 69 years of age. The gland, which was very much enlarged, was reduced to about the normal size, there being but a slight hyperplasia which persisted, but has not increased during the past six years.

Since treating the above case, the author has treated 50 cases of prostatitis of all types and with the result of absolute unrelapsing cures in 40 cases. Of the others there has been, in every instance, a large measure of relief, but extensive hyperplasia in a few cases has precluded the absolute recovery of the patient.

In cases of vesiculitis, especially those specific in character, the direct vacuum tube current, employing a vacuum tube adapted to the surface, is effectual not only in relieving the condition of tenderness and removing the congestion and engorgement, but also in divesting the parts of infection. The same principles applied by Dr. Edward Titus of New York has in his hands been successful in the treatment of gonorrheal rheumatism. These results are being obtained by a large number of American confrères, which in this age of surgical enthusiasm is reassuring.

Dysmenorrhea and subinvolution, the success of my treatment, which was first discovered, as in the case of prostatitis, while treating another condition, is a method which assures a future solution of one of the most distressing conditions of the female sex.

A patient 33 years of age, whom I had under observation for treatment of neurasthenia, was suffering from a retroversion of the uterus and had from the first menstruation suffered from dysmenorrhea, was treated for the associated constipation, as was the writer's practice at that time, by the wave current applied in the rectum. At the first administration it was impossible to pass the metal electrode (the same one as is used in the treatment of prostatitis) into the rectum for more than two inches when it came against the fundus which lay back upon the rectal wall. It was also noticed that at the outset the patient could endure a current measured only by a very short spark-gap—one inch and a half in length—which was lengthened gradually to about three inches at the end of the first administration. Each day the electrode was passed higher and the spark-gap lengthened. Before the end of the first week of daily administrations the patient could at the commencement of treatment take a current with a spark-gap of three to four inches, closing with a spark-gap of five to six inches. The treatment was continued daily except Sundays for one intermenstrual period. At the end of this time, on the day when the patient had said she could not be in for treatment, the writer was surprised when she entered his office and said that menstruation had begun with absolutely no pain or discomfort. Furthermore, the prolapsed organ had assumed its normal position and this patient now, five years later, has had no recurrence of dysmenorrhea. The neurasthenia coincidently disappeared. Since making this accidental observation, the writer and his wife employed the method in upwards of 40 cases and uniform success in upwards of 90 per cent.; failure alone occurring in those cases in which there was an acute flexion or a congenital stenosis. An advantage, as will be readily observed, of this method of treatment is that the applications are made through the rectum, the uterus being thrown into active contraction by the wave current from the rectal site of application. A slow rate of interruption is employed giving periods of contraction and release. The amperage of the current is such that the patient can sustain no injury or bad effect from their administration, and the site frees it from all objection in the virgin. These effects are obtained uniformly by a large number of confrères, who have adopted the method, verifying my observation.

Urethral caruncles are uniformly relieved and cured by the applications of a glass vacuum tube or metal sound connected directly to the static machine as were the metal electrodes in the preceding cases, otherwise known as the direct method of vacuum tube administration. As large a tube or sound should be used as will pass readily into the urethra and the administration should be made for from twelve to fifteen minutes daily. The result is prompt relief and a cure in most cases within ten days.

Neuritis.—The combined method of treating all forms of neuritis by the wave current and the static sparks was first introduced and published by the writer who was assisting Dr. Wm. J. Morton when the static wave current was first published.

After locating the site of the inflammatory process, which can usually be done by applying short sparks along the course of the nerve, which will produce extreme pain over the affected area, over that region place a metal electrode connected directly with the positive side of the static machine, following the same technique of the wave current as described in the previous cases. The electrode should be large enough to cover the extent of the involvement and little or no larger.

In *sciatica* an electrode of fairly thick flexible metal should be used. A square of about 10 centimeters is usually the right size. A striking evidence of the fact that we have or have not a lesion at the place of application is noted when the spark-gap is opened by the verbal complaint or facial expression of the patient when a spark gap of one or one and a half inches is allowed to discharge. The pain produced is of itself a diagnosis of the presence and location of the lesion, for normally a current measured by a spark-gap of four to six inches, producing intense local muscular contraction, will cause no discomfort whatever. Twenty minutes' administration,

lengthening the spark-gap gradually as the patient will tolerate it, followed by a few well-directed, indirect static sparks to the same site, constitutes the treatment of sciatica. The administrations should be given twice daily for two or three days, in severe cases of acute sciatica or brachial neuritis, and afterwards daily to give uniformly good results. To the present time I have treated 40 cases of acute sciatica of not more than two weeks' duration, in all of which the lesion has been located below the sacro-sciatic notch, with the result of a complete cure in all within ten days. In some of the cases which were treated very early a cure followed a few administrations.

In chronic sciatica it is often necessary to keep up the same treatment for several weeks, or even months, until all the exudate that is pressing upon the nerve structures has been absorbed. I pay but little attention to the pains along the course of the sciatic or the course of other affected nerves, making application only at the site of the lesion, unless for the nutritional effects or moral effect upon the patient, when sparks may be applied along the course of the nerve and over the atrophied muscles of the limb.

In *brachial neuritis, herpes zoster, and intercostal neuritis,* the same method is uniformly successful; also in the intrapelvic cases, which latter, however, require a much longer course of treatment because of the inaccessibility of the nerve lesion.

In *tic douloureux and Bell's palsy*, the writer's methods are practically the same as in the treatment of neuritis. Place a small electrode of pliable metal over the region of distribution of the trifacial nerve or the lesion of the branch affected. The patient should be seated in the chair upon the insulated platform with the hand supporting the electrode against the surface of the face, the elbow resting on a support, such as the arm of the chair. Administered in this way, it is only possible to use a maximum spark-gap of from one-half to three-fourths of an inch in length. The séance, which in the author's experience with the wave current is made uniformly for twenty minutes in the treatment of inflammatory conditions, is followed by a thorough application of the static brush discharge to the extent of producing active hyperemia over the site of the lesion. By this method cases of tic douloureux of not more than two weeks' duration terminate promptly in a cure in a few days. The treatments are given twice daily at first and then on alternate days until the pain will not return for an interval of more than twelve hours.

I have treated six cases of acute tic douloureux, five of not more than two weeks' and one of six months' standing, curing them all within the period of ten days. The result in the case of six months' duration was phenomenal, and the promptness of the relief quite unexpected. Chronic cases of tic douloureux in which organic exudates have formed within the bony canals are not amenable to this plan of treatment. I have, however, succeeded in some chronic cases by treatment with the *x*-ray.

Facial paralysis of peripheral origin, taken early, responds promptly to the same treatment as for tic douloureux.

Anterior poliomyelitis.—Looking at this condition from the point of view of a pressure paralysis with degeneration due to hyperemia or congestion of the cord, I, seven years since, instituted a method of treatment by applying the wave current over the portion of the cord corresponding to the paralyzed parts, and have found that in early cases the relief is salutary, the patients being restored in an incredibly short time, the improvement beginning usually with the first treatment. The little ones will bear the wave current with a spark-gap four to twelve inches long from a static machine having eight revolving plates, sufficient to induce an active effect upon the cord structures. An electrode not more than one inch in width is applied. It is customary in these cases to follow the static treatment with a nutritional administration of mechanical vibration to the affected parts. Cases of anterior poliomyelitis of from one to four months' standing have been greatly benefited by this plan of treatment; but it is plainly impossible to obtain a perfect result after sufficient time has intervened to allow destruction of the central neurons.

In cases of *tabes dorsalis* and other conditions of spinal nutritive and congestive derangement the employment of the static wave current with a narrow spinal metal electrode and employing a very long spark-gap—10 to 12 inches in length—has been productive of remarkable results when administered alone or in connection with the static sparks as instituted by Prof. Morton. I was the first to employ the wave current in this class of cases and feel certain that the very satisfactory results obtained in the large number of cases treated have been largely due to the effects of the static wave current and the general administration of the static sparks. In my judgment in this class of cases daily treatment for one month, followed by treatment on alternate days, is in most cases capable of bringing the disease to a *status quo* within a period of one year, controlling the pain within the first weeks and improving the locomotion to a marked degree, and in my experience, uniformly correcting the distressing bladder symptoms. I have effected these results in all cases which I have been able to keep under observation.

The effect of this current, administered as suggested, upon the spinal cord, is evidently to restore nutritive processes and to overcome acute or low-grade inflammatory conditions present in the structures. The same has been true in my experience in the treatment of conditions of myelitis and traumatic injuries involving the spinal cord, and in all traumatic congested conditions in which the spinal column is intact and in normal relation.

Traumatic arthritis, including sprains and conditions of uncomplicated synovitis, is remarkably amenable to this method of treatment. The anterior surface of the joint is covered with an electrode of flexible metal, avoiding contact with the flexor muscles of the leg or the gastrocnemius or soleus of the ankle joint because they are thrown with a mild current into contraction. The wave current is then administered followed by sparks over the soft structures or openings of the joints, avoiding the application of sparks to the bony prominences, which cannot respond, and to which applications are painful as well as ineffective.

Uncomplicated sprains of the joints are absolutely cured by this method in from three to five days and cases of synovitis involving the joints, of not more than two years' standing have in my experience invariably been cured in periods ranging from one to three months.

In *chronic synovitis* treatment should be administered daily for a month and later on alternate days until a cure is obtained. These results have been obtained by me in a large number of cases and have been verified by numerous other observers who have adopted the method.

The same method of application applies to the

treatment of *rheumatoid arthritis*, and with success in early cases, in which there has been no destruction of tissue. Attention must be given coincidently to any other physical condition which is impairing the general health; for rheumatoid arthritis is not curable in patients in whom exhausting pelvic conditions, nephritis, or some other enervating process is present. I have been successful by this method in the treatment of seven cases of rheumatoid arthritis, and one of Still's disease (treated with the wave current only), and have greatly improved the condition in many other advanced cases.

The above methods and results have demonstrated the great value of thermic administrations and the static modalities in the treatment of congestion, as based upon the principles incorporated in this paper, and I earnestly commend them to the members of the profession who are employing physical measures and to the profession at large.

INTEGRITY OF STEREOGNOSTIC FUNCTION AND OF ALL FORMS OF SENSATION IN A CASE WITH A LESION OF THE LEFT PARIETAL LOBE.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

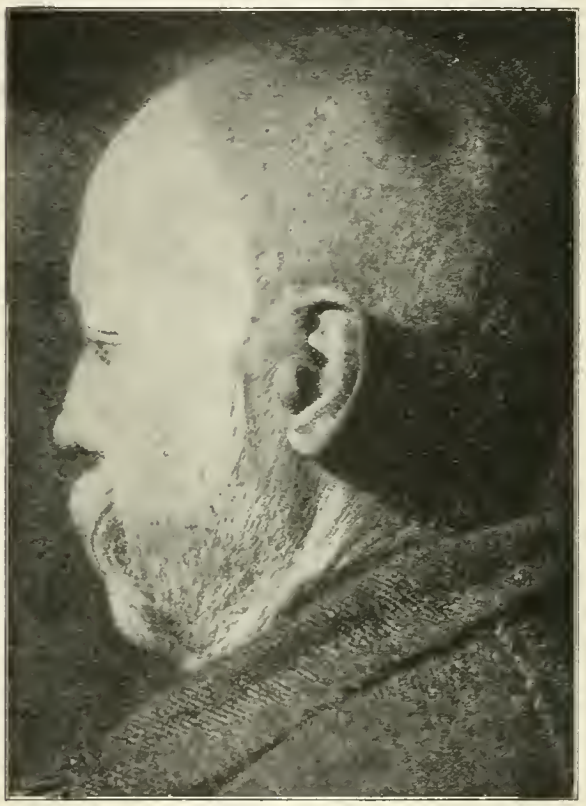
ASSOCIATE IN NERVOUS AND MENTAL DISEASES, JEFFERSON MEDICAL COLLEGE, EXAMINER OF THE INSANE AT THE PHILADELPHIA HOSPITAL, ETC.

Loss of stereognostic sense resulting from an organic disease is, according to the majority of observers, due to a lesion in the parietal lobe. There are abundant examples in the neurological literature supporting this contention. On the other hand there are also in existence facts which contradict the above view. Bonhoeffer,[1] for example, reports a case of a localized lesion in the middle third of the ascending frontal convolution with astereognosis. In Chipault's case[2] there was a lesion of the frontal portion of the Rolandic area. Verger and Abadie,[3] in one of their cases, found a sarcoma of the dura which compressed the parietal lobe and the angular gyrus so that the cortex was markedly flattened. In this case the general sensibility and the stereognostic sense remained intact. In Pierret's case[4] a softening of the parietal lobe produced only hyperesthesia which later on disappeared. Wernicke,[5] in a case of astereognosis of the right hand found a lesion of the middle third of the central convolutions. P. Marie and F. Moutier[6] report a case of a man aged 80, who during life could not distinguish objects by touch. Autopsy showed a bilateral softening of the lower surfaces of the temporo-occipital lobes.

These few examples, I believe, prove that there are cases of astereognosis with involvement of portions of the brain other than the parietal, also cases with integrity of the stereognostic function and lesions of the parietal lobe. The question, therefore, of localization of astereognosis cannot be at present satisfactorily settled. The case I am about to report is an additional proof of the fact that the post-parietal lobe is not exclusively the center for the stereognostic function. It also speaks against the view that a subcortical lesion causes persisting cutaneous anesthesia. Some hold the view that the limbic lobe is the sole cortical seat of the representation of cutaneous sensibility. Horsley and Schäfer also showed that circumscribed areas of anesthesia sometimes resulted from experimental lesions of the limbic lobe. The destruction of a large part of the parietal lobe in this case and the integrity of the remaining brain tissue are perhaps not against the limbic lobe view. The history is as follows:

N. L. G., aged 58, shot himself with a 22-caliber revolver on January, 1907, the ball entering the skull on the right at a point corresponding to the junction of a horizontal line drawn on a level with the roof of the orbit and of a vertical line drawn parallel with the mastoid process. The bullet was never extracted. The patient has no recollection of the attempt at suicide nor does he remember any event for some months following the shooting. All events prior to the shooting are easily recalled by him. He therefore suffers from anterograde amnesia.

His mentality in general is slightly impaired. It is difficult to concentrate his attention on any one subject for any length of time, but there is no confusion or incoherence. The patient orients himself well, takes an interest in everything, but there is a



From a photograph showing the site of operation.

delay in his responses to stimuli. Examination showed a scar on the right temple (place of entrance of the bullet). There was no palsy of the extremities or of the face. The reflexes, motor power, and sensations were all normal and equal on both sides. The speech was unaltered. He could hear, understand written or spoken words and he could write. He complained of vertigo, but there was no headache, insomnia, or vomiting. Since the accident the patient has had several attacks of loss of consciousness with convulsive movements of a generalized character. In none of the seizures unilateral spasms could be detected. The eye examination was practically negative with the exception of some senile choroidal degeneration and a high compound hyperopia.

The *x*-ray examination showed the bullet situated in the left parietal regions. As there was no evidence of meningeal irritation I supposed the bullet was beneath the cortex. In view of the involvement

*Read and patient exhibited before the Philadelphia Neurological Society, December 23, 1907.

of the parietal region a very careful test was made in regard to sensations. The sense of touch, of pain, temperature, and stereognosis were repeatedly examined by me before the operation and found to be normal and equal in the upper extremities.

Dr. J. C. Da Costa, who referred the patient to me for an opinion, operated upon my suggestion and the following is the report which he has kindly sent me:

The operation was performed on the left parietal lobe. The bullet was about half an inch from the cortex. The tissue surrounding the bullet was sclerotic except at one point in which there seemed to be a tear in the wall, a portion of brain tissue was adhering to the bullet which was free in this cavity. The cavity contained a material that resembled bloody serum. The opening of the skull was made by trephining. Careful palpation indicated an area of hardness. The cavity was opened with a knife and the bullet was found lying loose within the cavity; it was easily extracted. There was a great deal of venous bleeding from the walls and packing of the cavity with iodoform-gauze was necessary."

During the first several days after the operation there was quite a marked elevation of temperature. The patient gradually improved and made an uneventful recovery.

During convalescence I made repeated examinations for all forms of sensations. Changes of the latter were expected by me especially after the operation, as the cortex of the parietal lobe was considerably destroyed, but at no time could I detect the least alteration in any of the senses nor in the stereognostic function.

The patient's answers were prompt, normal, and equal on both sides. At this time the examination was exceedingly satisfactory, as after the operation there was a marked improvement in the mental condition. Incidentally I may mention that there was no recurrence of the epileptic seizure and the vertigo disappeared.

FRACTURES OF THE TIP OF THE OLECRANON PROCESS.

By FRANK E. PECKHAM, M.D.,

PROVIDENCE, R. I.

Since the Roentgen rays have come into use in connection with the treatment of fractures, it is no longer possible to treat such conditions by rule, but it is the duty of the surgeon to make an *x*-ray study of each case just as he makes a careful clinical examination. Thus there is presented a definite *mechanical* problem of getting two ends of bone into apposition or as near apposition as is possible. The mechanical problem includes not only the ends of bones but also (of very great importance) the traction of the different muscles and ligaments acting to pull the ends away from each other or one by the other. In the text books general rules are laid down for the treatment of all of these conditions, but as time goes on it is becoming very evident that each fracture must be studied as an entirely separate problem. For example, in fractures of the olecranon process, the rule laid down in the books is to put the arm up in complete or nearly complete extension. This is all right perhaps for most of the fractures and especially in complete fractures with *separation* of the fragments. There are cases, however, where the tip of the process is fractured and instead of a separation, the *x*-ray shows a riding by of the fragments, the tip being pulled upward and backward by the triceps muscle. From a study of the *x*-ray plate it is an easy matter to see that to put the arm in extension would aggravate the deformity and also that by flexing the forearm on the arm, leverage is created, and that with the fragment held as a fixed point by the triceps muscle and ligamentous attachments, there is a degree of flexion, varying in each case, which will bring the tip of the olecranon into perfect apposition with the other fragment. The two cases

Fig. 1.—Showing the fragment after reduction in Case I.

to be reported will illustrate this fact very nicely.

Case I.—A child nine years of age sustained a fracture of the tip of the olecranon of the left elbow in January, 1907. No *x*-ray was obtained before the reduction. This case was in the practice of Dr. Edward S. Brackett of Providence, who, after a careful clinical examination, decided that whatever the exact nature of the fracture, the apposition was best in the position of acute flexion. The *x*-ray picture showed such good apposition that it was deemed best to leave it in that position. See Fig. 1.) Without going into details of the early removal of bandages for manipulation, etc., it may be said at once that the result was absolutely perfect, both anatomically and functionally.

Case II.—A child of seven years of age, who had sustained a fracture of the tip of the olecranon of the left elbow, was under my care in September,

Fig. 2.—Showing fragment after reduction in Case II.

1907, at the St. Joseph's Hospital. The *x*-ray picture showed the small fragment pulled decidedly upward and backwards and it was evident that a flexion of about a right angle would probably bring the tip into good apposition. As is customary in my practice, a special internal angular splint was made, accurately fitting the arm; the arm was then placed at the proper angle on the splint by Dr. Hammond, the child being under complete anesthesia. The *x*-ray plates (Fig. 2) show the fragments to be in well-nigh perfect apposition. Without going into unnecessary details of early removal of splint, for manipulation, etc., Dr. Hammond, who had entire care of the case, obtained a perfect result, both anatomically and functionally.

The object of this short paper is not to urge the splinting of all elbows at an angle, either acute or obtuse, but it is to urge the careful clinical and *x*-ray study of each individual case and then treating accordingly.

Hygiene of Smoking.—Lieberman and Davidoes of Vienna, who have been investigating the action of nicotine on the body, have found that when rapidly smoked tobacco gives off more tarry substances in the smoke than when combustion is slower, and advise users of the weed to be deliberate in their enjoyment of it.

For an Esperantist State.—Professor Gustave Roy, an enthusiastic Parisian Esperantist, has announced his intention of endeavoring to convert into an Esperantist country a small commune on the outskirts of Belgium named Moresnet. It is seventy acres square and contains about 3,000 inhabitants. It is near the transcontinental railway lines from Constantinople to Ostend and London and from Madrid to St. Petersburg. Every one in Moresnet is to learn the universal language, so that travelers who will stop there may be understood, and Professor Roy hopes that from this little nation the whole world will be "Esperantized."

Feigned Eruptions in a Hysterical Patient.—The case is reported by C. J. White, whose patient was a coachman of forty years. In December, 1905, he burned his right middle finger while shaking down his furnace. The wound became septic, involving the bone, and in consequence the distal and middle phalanges were amputated. The stump healed in the course of six or seven weeks, but almost immediately became sore again, thus necessitating a second amputation at the metacarpo-phalangeal joint. In six weeks this second wound healed when there appeared at its site a thick crust, the size of a five-cent piece. At the same time a major portion of the back of the right hand and a half of the extensor surface of the forearm became involved by diffuse crusting lesions similar to the one just described. In November, 1906, the arm was incised in the anterior axillary line and the nerve stretched. After this operation there was quiet until some months later, when the man noticed itching in the arm and there appeared small red spots on the skin which, before attaining the size of a large bean, became covered with brown crusts and then slowly developed in size until they reached an area some two inches in long diameter. On examination the arm showed ten round or oval lesions covered with thick brownish crusts with depressed centers and concentric ridges, like the lamellation of an oyster shell. Around these crusts appeared a fine halo of pinkish skin, while from the lower edges of several of the larger lesions could be seen one or two linear streaks of slightly ulcerated, greenish or pinkish-red skin terminating in drop-like enlargements. These linear ulcerations were very important from a diagnostic point of view, and the author believes that they correspond well with the course of a caustic liquid influenced by gravity. On the dorsum of the right foot there were, in addition, several small lesions covered with blackish crusts. The crust at the site of the second phalangeal operation was blacker than the others and presented a deep crateriform surface, while from underneath pus could be expressed. This lesion, the man stated, had persisted from the time of the second excision. Physically the patient was well except for certain nervous symptoms which were highly interesting in their bearing on the case. Over the whole right half of the body the man was anesthetic, even the bulbar conjunctiva and nostril being insensitive to severe irritation. Motion of the right arm was much impaired, while the right patellar reflex was decidedly exaggerated.—*Boston Medical and Surgical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 18, 1908.

THE RELATION OF OPSONIC TO *X*-RAY THERAPY.

OPSONIC therapeutics has been conspicuously successful in certain diseases which have also been treated with equally conspicuous success by the *x*-rays. Examples of such diseases are lupus, acne, and glandular tuberculosis. The fact that the *x*-rays are of service in diseased conditions diverse in their pathology and causes, and that their antiseptic power is a negligible quantity, has led many observers to believe that the rays act by stimulating the production of opsonins in the body fluids. With this idea in mind, A. W. Crane (*American Journal of the Medical Sciences*, March, 1908) made cultures from several pustules in a case of acne and found the infectious agent was the *Staphylococcus pyogenes aureus*. He estimated the patient's index to this germ and then began *x*-ray treatment. After one exposure to the rays the index rose on each of the two succeeding days; on the fourth day there was a slight fall, so that a second treatment was carried out, the index again increased, and the acne disappeared a few days later. The patient evidently acquired, by some action of the *x*-ray, a specific immunity to the organism that caused the acne. Several cases of lupus, and one of tuberculous glands of the neck with low tuberculo-opsonic indices, were treated in the same way, with similar opsonic index changes and cure. In all the cases the *x*-rays ceased to raise the index when the infectious agent was presumably eliminated. In the patient with acne, who apparently had no tuberculous lesion, the opsonic index to the tubercle bacillus remained unchanged, showing that the *x*-rays do not appear to stimulate the production of opsonins for bacteria in general, but only for those in living tissues brought directly under their influence. He acquired good results with but few treatments, which he attributes to the careful timing of the latter, the opsonic estimation enabling him to give each treatment just as the positive phase began to decline.

Wright has shown that large doses of bacterial substances plunge the patient into the negative phase from which he may never recover. Crane thinks it quite possible that too many *x*-ray treatments have the same effect and that the sudden relapses, which *x*-ray operators sometimes see, might be explained in this way. He concludes that the repetition of exposures, as far as possible, should be governed by the duration of the negative and positive phases, and that in affections in which the disease-producing agent is as yet undetermined, one should be governed by analogy with those cases in which opsonic estimations can be made. It follows that as a rule the treatment should not be repeated oftener than twice a week, and probably usually at less frequent intervals. The immunizing substance set free under the influence of the *x*-rays is of necessity autogenous, which, Crane holds, is an advantage over opsonic therapeutics in which the vaccine is often made from a stock culture instead of from the bacteria from the patient. Furthermore, in cases in which the bacteriological cause is as yet unknown, or in which the disease-producing agents are not bacteria, the *x*-rays are nevertheless applicable.

Crane admits that he has carried his deductions and conclusions far beyond the limits warranted by the number of cases he reported. Nevertheless, he has opened up a fertile field for therapeutic endeavor.

LUDWIG'S ANGINA.

LUDWIG, in 1836, described a condition which he considered a morbid entity and which since that time has been designated as angina Ludovici. Regarding its general course and symptoms most observers agree, but various opinions exist with respect to its etiology and pathology, none of which have been generally accepted. In the February and March numbers of the *Annals of Surgery*, T. T. Thomas shows why and how this rapidly fatal infection acquires so dangerous a character. While the infecting organism is usually the streptococcus, alone or mixed with other organisms, he does not believe that the associated septic intoxication is more severe than that which results from streptococcus infections of the same grade, in other parts of the body. He holds that the dangerous character of this condition is due to its peculiar location, which favors dangerous extension to the respiratory tract. This opinion he bases upon a careful dissection of the floor of the mouth and upon the clinical and autopsy reports of over one hundred cases.

In ninety per cent. of the cases the cellulitis originated externally in the submaxillary region and not in the sublingual region, *i.e.* in the mouth. The primary focus in the great majority of cases was an insignificant lesion in the mouth, such as a carious tooth, whence the submaxillary gland became infected *via* the lymph vessels. Thomas showed that between the middle constrictor of the pharynx and the posterior border of the mylohyoid a deficiency exists in the muscular diaphragm which separates the mouth from the neck. The greater part of this deficiency is occupied by the submaxillary salivary gland which here projects into the floor of the mouth and is adjacent to the sublingual gland. The connective tissue in the submaxillary fossa is therefore directly continuous with that of the floor of the mouth. It is thus demonstrated how readily a cellulitis of the submaxillary region, regardless of the kind of infection, can become a Ludwig's angina by extension of the infection to the sublingual region and pharynx. When once the sublingual region and pharynx are involved the

anatomical conditions favor an early invasion of the larynx, since the direction of least resistance is backward.

Being convinced that the primary cellulitis is in the submaxillary region, Thomas warns against an incision through the mouth except for the relief of excessive swelling. He advises the submaxillary incision, and if frank suppuration is not found here, the mylohyoid muscle should be divided and the sublingual tissues exposed. On account of the added irritation of a general anesthetic to an already dangerously inflamed larynx he advises local anesthesia.

QUANTITATIVE ALBUMIN ESTIMATION BY ELECTRICAL CONDUCTIBILITY.

In 1887 Arrhenius demonstrated that the conductibility of electrolytes was diminished in the presence of a nonconductor. With this principle in mind and remembering that albumin was a nonconductor, Wassmuth devised a method for the quantitative estimation of albumin in urine. Under the supervision of Senator, R. Kohler recently (*Zeitschrift für klinische Medizin*, Volume 65, Nos. 1 and 2) tested the practicability of Wassmuth's method. Three hundred cubic centimeters of albuminous urine is brought to room temperature and acidified with one or two drops of a fifty per cent. solution of acetic acid. Then the conductibility of one-half the amount is estimated, while the albumin is removed from the other half by precipitation by heat. After filtering and making certain that all the albumin is precipitated, the conductibility of the filtrate is estimated. This ascertained, it is easily figured out in terms of percentage by how much the albumin reduced the conductibility of the urine. Kohler found that this latter figure divided by 16.6 would represent the percentage of albumin in the urine. Thus, if .009 represented the conductibility of the albuminous portion of the urine and .01 the conductibility of the portion from which the albumin had been removed, we can readily see that the albumin reduced the conductibility by ten per cent.; ten divided by 16.6 would then represent the percentage of albumin in the urine. Kohler found that the results thus obtained compared favorably with those obtained by Esbach's method, the one usually employed in the quantitative estimation of albumin. A decomposed urine, a diluted urine, or the addition of too much acetic acid interfered with the accuracy of the results.

Although Wassmuth's method permits us to estimate the amount of albumin in from ten to fifteen minutes, it is no more accurate than Esbach's, is more complicated, and requires an expensive apparatus. It is therefore impracticable for general use especially as an occasion seldom arises when we cannot wait twenty hours for a result, the time required with Esbach's albuminometer.

A New Method of Treating Syphilis.

Consideration of the fact that the apparent causative agent of syphilis, *Treponema pallidum*, is believed by competent observers to belong to the group of the protozoa, has led to a renewed interest in the method of action of mercury in the treatment of the disease. One assumption is that this agent, while not directly destroying the specific organisms, is yet able to damage them to such an extent that they readily fall a prey to the antibodies formed by the patient. Others hold that mercury acts chiefly in a manner comparable to that of the chemical catalysts in accelerating the reactions by which the spirochetes are destroyed, or through its property of encouraging the accumulation of leucocytes. Lenzmann (*Deutsche medizinische Wochenschrift*, March 5, 1908) is more inclined to the belief that the action on the microorganisms is a direct one, not unlike that exerted by quinine on the malarial plasmodium, and he has accordingly used quinine in fourteen cases of syphilis in various stages, in twelve of which the spirochete had been demonstrated. The results were sufficiently striking to encourage further trials, not with the view of displacing mercury from its well-earned place in the therapy of syphilis, but for the purpose of supplying what may be a useful adjuvant in certain cases. The mode of administration was by the intravenous injection of from three to eight c.c. of a 10 per cent. solution of quinine hydrochlorate in 0.75 per cent. salt solution, the injections being repeated at intervals of several days, until from four to five grams of the drug had been administered in the course of two or three weeks. In some cases the addition of nucleinic acid was used in conjunction with the quinine with the idea of stimulating the formation of leucocytes.

Mixed Infections in Typhoid Fever.

Although the occurrence of various severe complications in typhoid fever which cause the course of the disease to deviate from the typical form has frequently led to the suggestion that these were possibly due to a secondary blood infection with other organisms, the bacteriological proof of this supposition has not often been successful. Port (*Deutsche medizinische Wochenschrift*, March 26, 1908) describes four cases of his own, however, in two of which the *Staphylococcus pyogenes* was found in the blood as well as the typhoid bacillus, and in the others the colon bacillus and a diplococcus respectively. He has also found in the literature reports of thirty-eight similar cases, and is of the opinion that they occur more frequently than is commonly supposed, particularly in the so-called fulminating cases. Severe cerebral symptoms, excessively high temperatures, jaundice, petechiæ, chills, high leucocyte counts, and endocarditis are all manifestations that indicate the possibility of such a double infection and render a careful study of blood cultures desirable. In making this it is wise not to rely on the useful bile media alone, for the addition of this enriching agent inhibits the development of many other organisms and makes it easy to overlook their presence. Investigations in this direction have a practical bearing on the prognosis, for all the recorded cases of generalized mixed infection have ended fatally.

The Surgical Treatment of Hypertrophy of the Tonsil.

Hyperplasia of the tonsillar tissues, with its unpleasant secondary results, is so common that a generally applicable means of treatment calculated to correct the difficulty is much to be desired. There is reason to fear that the operative procedure commonly employed often fails of its purpose, the

cicatrical tissue that forms after tonsillotomy serving to interfere with the normal functions of the gland and thus impairing rather than fortifying its powers of resistance and defense. In the opinion of Dr. Chevalier Jackson, writing in the *Annals of Surgery* for December, 1907, few operations in surgery are so generally performed badly as those upon the tonsils. He considers tonsillotomy an easy but unjustifiable operation, while ideal tonsillectomy is an exceedingly difficult one. In his opinion the tonsil and its capsule should be dissected out completely down to its muscular bed, such hemorrhage as occurs being controlled by twisting the bleeding vessels by means of a long hemostat. Oozing from the wound may be simulated by bleeding from an open vessel concealed behind the anterior pillar of the fauces or retracted into the remaining tissues and covered by a layer of clot. Bleeding from vessels too small to be twisted or ligated can be checked by the insertion of a gauze plug in the wound between the pillars. Dr. Jackson prefers to use scissors in operating, exerting traction on the top of the tonsil with forceps and after the first incision enucleating the gland in its capsule by blunt dissection. The anterior pillar is elevated by means of a special retractor and the blood-vessels are twisted with the aid of a hemostat. If the bleeding persists or recurs and threatens to be fatal, ligation of the external carotid should be undertaken.

Puerperal Infections.

It has long been recognized that in certain cases of puerperal sepsis local treatment of the uterus by curettage or even by gentler measures is decidedly contraindicated. More extensive resort to bacteriological examination of the uterine and vaginal discharges, and particularly the making of blood cultures, have shown that these were instances of true septicemia due to a streptococcus. Veit (*Berliner klinische Wochenschrift*, March 23, 1908) emphasizes the importance of the examination of the lochia in all cases and states that the vaginal secretion suffices for the purpose of making cultures on Schottmüller's blood agar medium. If the presence of the hemolytic streptococcus is discovered by this means all local treatment must be interdicted, as manipulations about the internal genitals always involve the risk of producing new lesions likely to be the portals of entry for the germ into the blood. Blood cultures should be made, and if positive, general measures such as the injection of antistreptococcus serum, infusions of salt solution, and alcohol should be administered, though the outlook is dubious in these cases. The value of operative treatment by ligation of the pelvic veins is also questionable when there is a blood infection. On the other hand, if the elevation of temperatures is due to the presence of saprophytes and decomposing material in the interior of the uterus, this organ should be stimulated to contract, and if the symptoms persist, energetic local treatment should be instituted. In these cases the prognosis is usually good, but the uterus must be promptly emptied and disinfected, while antitoxin is wholly useless.

Nervous Diseases Among Soldiers in Time of War.

In the beginning of the Japanese war the Russians had made no special preparations for the care of the insane, and not until the number of patients afflicted with nervous diseases in the various general hospitals reached 500, was a special psychiatric hospital established. All the patients were then sent to the latter hospital from where they were sent back to Russia if they had not improved in two weeks. Two smaller hospitals were established along the home route to receive patients who became worse on the way to Russia. In the *Allgemeine Zeitschrift für Psychiatrie* (Volume LXIV, Nos. 2 and 3), Avtokratov gives a detailed description of the psychiatric hospitals and the mode of transporting the patients. Over 1,600 soldiers were afflicted with some nervous ailment, *i. e.* three and one-half per cent. of all the sick in the army, and the mortality was twenty-one per cent. Among the officers alcoholism heads the list of diseases, then come paresis and neurasthenic psychoses. It appears that latent psychoses or those with only prodromal symptoms develop rapidly during war; thus epilepsy developed in persons who never had any convulsions previous to the war. The fact that in peace paresis, and in war alcoholism, heads the list of nervous diseases among officers, he attributes to the fact that even small quantities of alcohol are injurious when the individual is in a stage of excitement and overexertion; in fact officers developed alcoholism who, previous to the war, had never indulged in alcoholic beverages. The greater majority of the patients were improved at the end of a week and were cured in a month. Avtokratov's report is of great value, inasmuch as it also points out all the errors made, and should, therefore, prevent many mistakes in future wars.

News of the Week.

State Board of Charities.—The State Board of Charities has reelected President William R. Stewart and Vice-President Dr. Stephen Smith, both of this city, and reappointed Commissioner Denis McCarthy of Syracuse a member of the State Probation Commission from the State Board of Charities. The board has also appointed James H. Foster of this city inspector of records and accounts in place of Richard W. Wallace, who has been promoted to be superintendent of inspection.

Banquet to Dr. Koch.—At the dinner in honor of Dr. Robert Koch held at the Waldorf-Astoria last Saturday night about 400 guests, including many of the best known medical men of this and other cities, were present. Dr. Carl Beck presided, and among the speakers were Dr. Koch, Dr. W. H. Welch, Dr. Abraham Jacobi, and Mr. Andrew Carnegie, who has recently given the sum of 500,000 marks for the Koch institute to be founded in Berlin for the study of tuberculosis. Dr. Koch early in the week left for Niagara Falls, and after stopping in Chicago and St. Louis, will go on to Japan.

The Medical Club of Philadelphia held a reception on the evening of April 10 in honor of Dr. Samuel G. Dixon, Health Commissioner of the State of Pennsylvania, Dr. Lewis S. Pilcher of Brooklyn, and Dr. Robert Koch of Berlin. Dr. Dixon spoke of the efforts of the State to suppress tuberculosis, especially by means of dispensaries and camps, of the great saving of life effected by the free distribution of diphtheria antitoxin among the poor, and by measures taken to prevent the pollution of streams and waterways. Dr. Koch was unable to be present, but sent a letter. Dr. Pilcher paid a tribute to the great names recorded in the annals of Philadelphia medicine.

Water Supply Conference.—An interstate con-

ference of Water Commissioners was held in this city last week at the instance of the New York State Water Supply Commission, with the object of initiating a national conference to which may be called members of all the Water Supply Commissions of the various States and Territories, together with the Forestry and Inland Waterways Commissions. Steps were taken for the formation of a national conference and the scope of such a project was discussed. Another matter considered was the question of joint action by the States of New York, New Jersey, and Pennsylvania, for the control of the Delaware River, which forms the boundary line between these States, and the prevention of floods. It was also stated that an abundant supply of water for New York City could be obtained at a small expense and within a short period if the authorities of Connecticut and New York could agree upon a plan which would permit this city to tap the Housatonic River and its tributaries.

Nomenclature of the Proteins.—By order of the American Physiological and American Biochemical Societies a series of recommendations have been published in regard to the nomenclature of the protein bodies, which are in part as follows: First: The word *proteid* should be abandoned. Second: The word protein should designate that group of substances which consists, so far as at present is known, essentially of combinations of *a*-amino acids and their derivatives, *e.g.* *a*-amino-acetic acid or glycocoll; *a*-amino propionic acid or alanin; phenyl-*a*-amino propionic acid or phenylalanin; guanidin-amino valerianic acid or arginin, etc., and are therefore essentially polypeptids. Third: That the following terms be used to designate the various groups of proteins: I. Simple Proteins.—Protein substances which yield only *a*-amino acids or their derivatives on hydrolysis. This group includes albumins, globulins, glutelins, alcohol-soluble proteins, albuminoids, histones, and protamines. II. Conjugated Proteins.—Substances which contain the protein molecule united to some other molecule or molecules otherwise than as a salt. This group includes nucleoproteins, glycoproteins, phosphoproteins, hemoglobins, and lecithoproteins. III. Derived Proteins.—1. Primary protein derivatives. Derivatives of the protein molecule apparently formed through hydrolytic changes which involve only slight alterations of the protein molecule. This group includes proteins, metaproteins, and coagulated proteins. 2. Secondary protein derivatives. Products of the further hydrolytic cleavage of the protein molecule. This group includes proteoses, peptones, and peptids.

Requirements for Admission to the College of Physicians and Surgeons.—The following changes in the requirements for admission to the medical department of Columbia University have been announced by Dr. Samuel W. Lambert, Dean of the Faculty: The present requirements for admission to the first year class will be continued without change up to, and including, the admission of the class which enters in September, 1909, and thereafter the requirements for admission to the first year class will be as follows: All candidates for the degree of Doctor of Medicine desiring admission to the first year class must present (1) the Medical Student Certificate of the Regents of the University of the State of New York, and (2) also one of the following qualifications: (*a*) The completion of not less than two full years of study in an approved college or scientific school, which course must have included instruction in the elements of physics, inorganic chemistry, and biology; or (*b*) Graduation from an approved college or scientific school, or in lieu thereof a bachelor's degree in arts or science or its substantial equivalent conferred by an approved institution in Great Britain, France, or Spain, or graduation from a gymnasium in Germany, Austria, or Russia, or the completion of a course of study equivalent thereto, or (*c*) In lieu of either of the above, present such evidence as the faculty may require, to prove exceptional fitness to undertake with advantage the study of medicine. In regard to admission to advanced standing, to go into effect immediately, it is announced that candidates who have completed one or more years of study in an approved medical school, and apply for admission to advanced standing at the College of Physicians and Surgeons, will be admitted to the standing to which their record in that medical school would admit them, and be given credit for all courses satisfactorily completed therein, on presentation of proper certificates covering the same; provided that the candidates before beginning the study of medicine have fulfilled the requirements for admission demanded by the College of Physicians and Surgeons.

Army Canteen Association.—An organization having for its object the reintroduction of the canteen at United States Army posts has been incorporated in this State. The office of the association is at 70 West Forty-sixth street.

Honor for Miss Nightingale.—The Corporation of the City of London by a recent vote has conferred upon Miss Florence Nightingale the freedom of the city, a distinction never before bestowed on a woman except in the case of the late Baroness Coutts.

Appointments of Drs. Meyer and Richards.—Dr. Alfred U. Richards, of Columbia University, has been made Professor of Pharmacology, and Dr. Arthur W. Meyer, of Johns Hopkins University, has been made Professor of Anatomy in the Northwestern University Medical School, Chicago.

Dr. Dudley Jackson, who for five years was superintendent of Wesley Hospital, Chicago, recently resigned this position and has resumed private practice.

Professor Lassar's Dermatological Collection.—The dermatological collection of the late Professor Lassar, comprising more than 2,000 colored casts of skin lesions, has been presented by his widow to the city of Hamburg, Lassar's birthplace, where it will be installed in the St. George Hospital.

Typhoid Fever Near Boston.—Typhoid fever is epidemic in Jamaica Plain, over two hundred and fifty cases having been reported within the last two weeks.

Measles in Brooklyn.—An unusual number of cases of measles is being reported in Brooklyn, the records for two days last week showing one hundred and sixty-four new cases. During the month of March more than 2,500 cases were reported, as against 600 cases for the same period last year.

Mount Sinai Hospital Fellowship.—The George Blumenthal, Jr., fellowship in pathology has been founded in this hospital with an allowance of $500 yearly.

Gift to University of Michigan.—The sum of $1,000 has been given to the library of the University of Michigan at Ann Arbor, by Mr. Peter White of Marquette, for the purchase of rare medical works.

Two Indiana Medical Colleges Merged.—The Indiana Medical College (the School of Medicine of Purdue University), and the Indiana University School of Medicine have merged by agreement with the Indiana University School of Medicine. The name of the new school is "The Indiana University School of Medicine."

Fordham Hospital.—The Medical Board of Fordham Hospital announces that applications will be received for the following positions, in the Out-Patient Department: One assistant attending surgeon, two assistant attending physicians, and one attending physician for the *x*-ray department.

Harvey Society Lecture.—The ninth lecture in the Harvey Society course will be given at the New York Academy of Medicine on Saturday evening, April 18, at 8:30 P.M., by Professor Alonzo E. Taylor, University of California. Subject, "The Role of Reversed Ferment Reactions in Metabolism."

Congrès de l'Association des Médecins de Langue Française de l'Amérique du Nord.—This organization will hold its fourth annual congress in Quebec, July 20 to 22, 1908, in conjunction with the celebration of the third centennial of the foundation of the city of Quebec. The president of the association is Dr. Arthur Simard of Quebec, and the secretary is Dr. Albert Paquet of Quebec. Communications relative to the congress should be addressed to the treasurer, Dr. N. A. Dussault, 28 Rue Ste.-Ursule, Quebec.

The American Pediatric Society will hold its twentieth annual meeting on May 25, 26, and 27, 1908, at Delaware Water Gap, Pa., under the presidency of Dr. Charles G. Kerley. One session will be taken up in discussing the serum treatment of epidemic cerebrospinal meningitis. Dr. Simon Flexner will open the discussion, and Dr. Dunn will give the results of this treatment as observed in the Children's Hospital of Boston. There will be a symposium on the influence of cold air in the treatment of disease, the diseases to which it is applicable, and the degrees of temperature which should be used in the different types of disease. Drs. Northrup and Graham will open the discussion. Epidemic anterior poliomyelitis will be discussed by Drs. Koplik and Le Fetra. Dr. Holt will read a paper on recent diagnostic methods in tuberculosis of children. Members are requested to send, at their earliest convenience, the titles of their papers to Dr. Samuel S. Adams, 1 Dupont Circle, Washington, D. C.

Medical Society of New Jersey.—The date of the coming meeting of this society to be held in Cape May has been changed to June 18, 19, and 20, 1908.

Boston Medical Society.—At the annual meeting of this society on April 7 the following were elected as officers: *President*, Dr. William F. Gay; *Vice-President*, Dr. A. J. Hurwitz; *Secretaries*, Drs. Fred Bailey and L. A. Herman; *Treasurer*, Dr. Rufus K. Noyes.

New London County (Conn.) Medical Society.—The following officers were elected at the meeting of this organization held in New London on April 2: *President*, Dr. M. E. Fox of Uncasville; *Vice-President*, Dr. G. H. Jennings of Jewett City; *Clerk*, Dr. E. C. Chipman of New London.

Memorial to Purkinje.—A bust of Purkinje, the eminent physiologist, has been unveiled in the physiological laboratory of the University of Breslau.

Obituary Notes.—Dr. George W. Griffiths of Louisville, Ky., died on April 11 at the age of fifty years. He was graduated from the Long Island College Hospital in 1866, and had practised in Louisville for forty years. He was chief surgeon of the Louisville and Nashville Railroad and trustee of the University of Louisville.

Dr. Chester G. Higbee of St. Paul, Minn., died of cerebral hemorrhage on April 2 at the age of seventy-three years. Dr. Higbee was born in Pike, N. Y., going to Wisconsin in 1846 with his parents. He was graduated from Hahnemann College, Chicago, in 1870, and then practised at Red Wing for several years, after which he went to St. Paul in 1874.

Dr. James C. Gleason of Corona, Cal., died on March 28 of nephritis at the age of sixty-three years. He was a native of Illinois and received his medical degree from the University of Iowa Medical College. He had practised in Corona for over twenty years.

Dr. M. A. Carrol of Ludington, Mich., died on April 1 at the age of fifty-four years. He was born in Ohio and was graduated from the Western Reserve University Medical College in Cleveland in 1880. He was county coroner at the time of his death and had held numerous other official positions.

Dr. H. P. Brockett of Melvern, Kan., died on March 30 of appendicitis at the age of twenty-five years. He was born at Cottonwood Falls, and was graduated from the Kansas Medical School in 1906. His brothers are Dr. W. T. Brockett of Mayetta, and Dr. F. P. Brockett of Lebo, Kan.

Dr. Peter Dockler of Onaga, Kan., died on April 2 at the age of one hundred and three years. He was born in Paris, and after serving as surgeon in the French Army went to New Orleans in 1840. He was one of the first residents of Onaga, and prescribed for patients within a few days of his death.

Dr. Edmond F. Thomson of Belchertown, Mass., the son of Dr. George F. Thomson, died on March 29 at the age of forty-one years. He was born in Belchertown, and was graduated from the College of Physicians and Surgeons in this city in 1892. He practised in New Haven for some time, but returned to Belchertown several years ago.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth correctly the nature of the ailments therein described, with remarks on their appropriate treatment.

———, California, December 8, 1906.

Dear Doctor:

I am writing to you to get an opinion concerning a colleague who has come out here to live—or rather to die, according to his statement. He was formerly a practitioner in Philadelphia. It is tempting to say here something about the pace there in relation to his disease, but I refrain. His story is a long one and I confess that I do not see clearly his way out. It is very likely because of my small experience with such cases, that I feel the necessity of leaning upon some one to aid me in forming a judicial opinion. The physician's story, as I have been able to put it together, and to abbreviate it (for if I were to write all that he has told me I should have to defer writing until next summer's holiday), is practically as follows:

He is 36 years old, celibate, of New England birth

and education, and up until the time he withdrew from active work in the profession, now about 18 months ago, he had had good health. After about ten years in active general practice he began gradually to specialize more or less in gynecology. His practice was never very large, he says, but it was very engrossing. It is not so easy for me to apprise you of just what he means as it would be if you knew the man. He has that indescribable something which, when doctors have it to give, patients take from them at the expense of their vitality. He did not hesitate to assume responsibilities, to give endless encouragement, sympathy, and care to everyone who came within his sphere, it mattered little whether he had a personal liking for them or not. He was successful, but not immoderately so, although he was a very hard worker both with his patients and with his books.

When he was 30 years old he had an attack of inflammation of the prostate which resulted in abscess necessitating a good deal of surgical treatment which was given to him by a very competent man, Dr. ——. He made a fairly satisfactory recovery, although he was still in the surgeon's care when two incidents bearing upon his present illness transpired. One was a shocking accident to a member of his immediate family, and the other was the protracted and fatal illness of one of his most beloved and important patients. This illness was a painful and tedious one, during which the doctor was most untiring in his attentions. It was at this time that he began to complain of physical and mental torpor, of a sensation of emptiness in the head, and of unaccountable depression. He decided to take a holiday in the shape of an ocean trip. He went to England and although he says he was improved somewhat by the trip, nevertheless, he consulted a physician about his prostate who advised him to have deep urethral injections. He took the treatment for a period of six weeks. During this time he became depressed, particularly because of a pain which had developed in the abdomen to the right of and below the umbilicus. The pain was more or less constant, a dull, exhausting ache. Soon other symptoms developed, particularly disturbed sleep, more or less headache, considerable neuromuscular weakness, and worst of all, mental depression. He consulted another physician but not being impressed by the quality of his advice he went to Paris and sought the opinion of a well-known professor of nervous diseases, who suggested that he should go to the South of France and take a cure, principally hydriatic. He tried this for a while and with some benefit, but as he was worried about his affairs at home he decided to come back and devote himself in a quiet way to his practice. He undertook work only to find that he was mentally and physically unequal to it. He was so absorbed in the consideration of his own disagreeable sensations that he could not give attention and concentration to the various things that demanded them. More than that, he seemed to have developed a very considerable amnesia which added to his depression for he became convinced that it meant some disease of the brain, such as general paresis or arteriosclerosis, which his physicians had not detected. Inclination to work was often felt but he did not have the ability to make himself do it, and when he got himself into work he soon became so exhausted that he felt prostrated. With this came a settled conviction that something much more serious had befallen him than any of the physicians whom he had consulted had yet discovered, and he began to seek the advice of one consultant after another. The result was a variety of opinions which but added to his anxiety and his apprehensiveness. The pain in the side he was convinced resulted from some malignant process; the trouble of the prostate gland was of such a nature that treatment could not overcome it, the slight polyuria was magnified into a symptom of prime importance. Occasionally he complained of dizziness, of palpitation, of a fluttering sensation in the abdomen, and worst of all, of periods of acute anxiety. At these times he would become so solicitous concerning his immediate safety that it was necessary to call a physician, and oftentimes a new one, to calm his fears. During this time he received a great deal of treatment from a genitourinary surgeon, from an internist, and from a general practitioner. He made some progress toward recovery, but never enough to permit him to carry on his professional work. He gradually became convinced that his life of activity had been lived and that he must give himself up to chronic invalidism for the remainder of his days. He became preoccupied about himself in the most typical hypochondriacal way, and the manifestations of selfishness which he displayed are too numerous to mention. Finally he consulted a physician who advised him to come out here and here he has settled, surrounded apparently by every comfort, provided almost entirely, I am told, by his relatives, and ministered to by a devoted sister who, however, has a devoted husband in the East who thinks he is not getting a square deal.

I was called in to see this colleague during one of his anxiety attacks and got interested in his condition. I have since been frequently to see him. He says that he is very anxious to get well, but he thinks the age of miracles is past, that he has done everything that has been suggested and, despite this, witness his present state. He has not enough money to support himself in any comfort nor has he prospects of such, but despite this he accepts the sacrifices of the various members of his family and is preparing to die.

His principal symptoms as far as I make out are headache, disturbed sleep, physical apathy and weakness, indigestion, constipation, occasional dysuria, depression of spirits, enfeebled intellectual capacity manifest by inability to concentrate, to recall quickly, to associate, and to exert the will-power, emotionalism, and selfishness. Everything that comes up for comment, discussion or debate, is brought to the threshold of his Ego for comparison and application. Common incidents of daily life that do not apply to him at all are treated as new and potent sources of injury to his prospects of recovery.

I have looked him over as carefully as I can and although there is evidence of disordered function of different organs and systems of his body, I cannot find any evidence of disease. His digestion is surely not in good condition, elimination from the skin, kidneys, and bowels is inadequate, and the extremities are cold, the skin oftentimes clammy, and his complexion has a color or hue that does not strike one as the color of health, but his circulation, heart sounds, blood-pressure, and blood itself are all in fairly normal condition.

I forgot to say to you that at the present time he is under the care of an osteopath here. He says that he has exhausted the resources of the regular profession and that it does not make any difference to him what the osteopath thinks about dislocations of his vertebræ so long as he feels a little better after the treatment. He has given up the idea of ever being restored, but he does not scorn being made to feel a little better en route to translation.

What I wish to get from you is the expression of an opinion as to the nature of his ailment and how to proceed in the accomplishment of his cure. If you will outline a plan of treatment for me I shall try to carry it out and let you know what success I have.

Yours faithfully,

New York, December 15, 1906.

Dear Doctor:

I have read the description of your patient and I hope I shall be able to say something to you that will aid you in restoring him to a career of usefulness and that you may obtain the earnest for your service that is one of the greatest joys of life to members of our guild, viz., the gratitude of a fellow creature reclaimed from a life of invalidism.

I should like to have heard something of your patient's ancestry and of his environment during the years when his character was in the mold. We neurologists early became apprised of the fact that the rift in the lute of some ancestor, by and by makes the music mute in the descendant (with apologies to Tennyson). Indeed, perhaps there is no disease whose course and eventuation is more illumined by a knowledge of the forbears of the individual than neurasthenia, from which your patient suffers, except one with which it is frequently confounded, psychasthenia. This last-named disease may be unfamiliar to you as recognition of it has disseminated slowly. Beard struggled for 25 years to get neurasthenia accepted as an autonomous disease, and scarcely had he got the colossus measured than the dismemberment of it was begun. You know the vast literature that has grown up around it in every land, especially in Germany, the country in which it was at first most coldly received. To-day it is held by many leading neurologists in this country and abroad that neurasthenia as an autonomous disease does not exist, but that there is a symptom-complex subject to slight variation in its constitution but to great variation in its intensity, which is the expression of fatigue or exhaustion of the entire nervous system and its appendages to which the name neurasthenia is properly applied. This symptom-complex may be the result of many widely different causes, but the immediate antecedent is the expenditure of energy that cannot be spared. This expenditure may be a voluntary one, an attempt to accomplish some specific purpose, such as acquiring fame or fortune, or involuntary, an effort to counteract disease or disorder of some important function, or to withstand shock, ignominy, or grief. Infringement of what are called Nature's laws (to be made out in many cases of neurasthenia comes under this head. Some individuals have a vast amount of energy and a large capacity for generating it, others have not. Some individuals tolerate frequent and protracted demand upon their physical and emotional spheres, others do not. Some persons take alcohol all their lives with impunity, others cannot indulge in it a short time without suffering. The individual is the important factor to be considered when the cause of the disorder is being sought.

The neurasthenia that I recognize is characterized by definite physical and mental symptoms, and they are those enumerated in the closing paragraphs of your letter. Naturally, different individuals describe their so-called feelings and sensations differently, according to their temperament, capacity for expression, their imagination, etc., and this holds true for individuals who are neurasthenic. But fundamentally the symptoms are subject to but little variation save in intensity and duration, and these qualities may be accounted for just as they are in scarlatina, pneumonia or other accidental disease. I look upon neurasthenia as an acquisition, not an inheritancy. I look upon psychasthenia as an inheritancy, not an acquisition. Therefore, neurasthenia rarely if ever occurs until after maturity. Psychasthenia almost invariably shows evidence of its existence before that epoch. There are borderland cases, and one of them is described in a letter I append to this reply. Charcot used to show us, when I was a student in Paris, cases of what he called congenital or idiopathic neurasthenia and he distinguished them very closely from acquired neurasthenia. This was another indication of his clinical clairvoyancy. Congenital neurasthenia nowadays is pronounced psychasthenia.

Psychasthenia, the disease (I repeat, at the expense of wearying you, I fear) from which neurasthenia must always be distinguished, if we are to have full measure of success in treating these disorders, is, on the other hand, not an acquired disease. It takes its origin in soil that has been prepared before the birth of the individual and indications of the existence of abnormalities in the victim's mental make-up are frequently present while he is still a child. Such indications are aboulias, phobias, scrupulosity, literalness, obsessions, etc. This predisposition evolves unaided, spontaneously. Incidents slight and trivial to the average individual produce intense results. The chief reason why the physician should distinguish between neurasthenia and psychasthenia, is that one is eminently curable, the other is not. Neurasthenia is a disease that yields almost uniformly to appropriate treatment, and I have no hesitation in saying to you that your patient will recover.

The plan of treatment that you ask for is a simple one: Improve his nutrition and praise him. Functional disease cannot withstand the first, and feelings of incapacity, insecurity, and inadequacy fall before the latter as Tyre fell before Alexander. There are many ways of accomplishing the first: superalimentation if the digestive apparatus will take care of it, massage, resistance exercises, tonic baths, Nature's soft nurse, etc. Indeed, I am not at all sure that the latter alone will not be adequate if you give her full possession, and the way to do it is to have the patient sleep out-of-doors. I am of the opinion that anyone with neurasthenia who will stay in the open air all the time and whose insomnia can be overcome will soon recover. At least, I should like to be reduced to treating everyone who comes to me with neurasthenia in that way.

What shall I say to you about food? Give him food that agrees with him and give him plenty of it. The important thing is to have a diet schedule. It is a valuable disciplinary measure for the patient. If he gains from one to three pounds a week he is going on favorably. If he does not, milk, eggs, and other easily digested, nourishing foods need to be pushed.

Shall you put him to bed and give him a rest cure? I am against it. One has to do it occasionally with patients whose neuromuscular tone is very low, but in all other cases I am opposed to it. A definite hour for a tonic bath, another for resistance exercise, or massage, for reading or being read to, for taking food, for resting, etc., will help to dissipate time, and will at the same time tend to convince him that every effort is being made to restore him to health. Neurasthenics take their symptoms and themselves most seriously and it has an excellent moral effect upon them to treat their symptoms as

if you were engaged in a combat with a foe worthy of your steel. Moreover, such systematic treatment is bound to relieve some of the symptoms, and this relief can be used as an example of the way in which the symptoms will disappear and the disease be gradually overcome. If you are able to instill into his soul the element of hope you have gone a long way toward making him well, even though he has got into the hypochondriacal stage of his disorder.

I counsel you to give him no local treatment even though you may be convinced that his prostate is not entirely normal. The benefit to be gained from such treatment is so immeasurably outweighed by the effect which it has to further concentrate his mind on a portion of the body from which come disagreeable sensations, that it is much more expedient to disregard it altogether..

So far as drugs are concerned, I wish only to say to you that practically they are unnecessary in the successful treatment of neurasthenia, save occasionally to counteract some disagreeable symptom such as stomach hyperacidity, insomnia, or constipation. These symptoms and all the others of neurasthenia may be overcome by appropriate dietetic and physical measures, but it takes some time to do it and meanwhile, if the patient's comfort demands it, they may be counteracted by drugs. What I really want to say is that no systematic drugging should ever be undertaken in neurasthenia. The habit of giving bromides and other sedatives, and of giving strychnine and other stimulants for a long period is in my judgment pernicious. If these statements were not founded in the experience of treating many hundreds of cases of neurasthenia and so-called neurasthenia, I should suspect them of being tinged with arrogance and dogmatism.

If your patient was suffering from psychasthenia instead of neurasthenia, I should have to dwell at great length upon what we neurologists call the moral treatment. I interpret him as a pure neurasthenic, so I leave it to your own judgment to formulate a plan for encouraging him and picturing the pisgah sights of the future when he shall be entirely restored to health.

Yours very sincerely,

———, Texas, Nov. 8, 1900.

Dear Sir:

I would like you to advise me as to the following case. At the age of 23 years (I am now 32 years old) of age, I developed a *severe* case of neurasthenia. Neurotic temperament. There is a history of masturbation when young. As far as I can remember the habit was not indulged in to any great extent, but was probably a great factor in the production of the trouble. I graduated in medicine when young, 19, and I was a surgeon in the army at 21 in charge of a large railroad hospital. When the trouble first began I started to consult you, but when I arrived in Baltimore I was in such a bad mental condition that I consulted Dr. ——, who sent me to a sanatorium for about two weeks, and then back to work. He informed me that I would gradually get better and better until I would soon be fully restored. I wrote him a number of letters, but he treated me with utter contempt. Then you will recall that I wrote to you. You advised me to place myself in the care of some colleague of good common sense and judgment, and to follow his instructions implicitly, but, like an infernal fool, I have endeavored to treat myself. I have drifted into a hypochondriacal melancholic condition. It seemed as if the disease prevented my seeking the proper relief. I have traveled extensively, taken all forms of treatment, and went on a ranch for a while, but could not remain there as the life did not appeal to me. For five years, unrelieved by the slightest relaxation, I have suffered untold agony. I was told by an alienist that if I would go to work I would get well. For the last two years I have been practicing here and am doing fairly well and I know I could win out if I could get well. I presume that I am a sexual neurasthenic, as the principal symptom has been a disturbance of the sexual sphere. What I desire to be informed is if you can be of any permanent help to me. I do not ask a complete restoration. The past with its horrible tortures has made such a mental impression that I am at a loss to understand how you would proceed to treat me. I do not want any more sanatoriums—nor promises that cannot be backed up by results.

What would you charge to treat a case of this kind? Make it reasonable as possible, as you yourself know how I am handicapped. I am a pretty disagreeable patient to handle. The case is a chronic one, and will require a line of treatment that I have not yet received. Had I been treated at first as you suggested, I would have been in a far better condition. Assuming from facts stated above, if you desire to undertake the case, we will make more definite arrangements. I am very busy just now but will try and get off at a later date. Promises are like pie-crusts, easily broken, so kindly do not answer this letter if you can not help me. I will take any form of treatment you advise. I understand you are peculiarly adapted to the handling of degenerates, and I would like to have one more chance.

Pardon this long letter, it is the first written to any doctor in a number of years.

Yours truly,

[Psychasthenia and hypochondria will be discussed later.—Ed.]

Correspondence.

THE RAY BROOK SANATORIUM.

To the Editor of the Medical Record:

Sir:—It is utterly futile to attempt to answer every unjust and unreasonable criticism of the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis at Ray Brook. Since the earliest organization of that institution criticisms of its every effort at location, of its architectural construction, and of its administration have followed a nearly unbroken sequence. Unfortunately criticism is not always without bias and is frequently made without a full understanding of the surrounding conditions.

The well-known disposition of the Medical Record for fairness compels a reply to many of the statements made in your editorial, "The Ray Brook Sanatorium," in your issue of April 4.

The Board of Trustees at Ray Brook is not made up of active or even nominal politicians. There is at least a majority of independents or reformers in politics among the board. There is not now, nor has there ever been, any open conflict between the Ray Brook Board of Trustees and the Civil Service Commission, and the Board of Trustees are not seeking now or at any time the repeal or modification of a single section, or a line, or a letter of the Civil Service laws of the State. It is true on the other hand that the Board of Trustees have advised the reduction of one year—from six years to five—as the post-graduate experience required of a candidate for the superintendency of the Ray Brook State Hospital. This action was taken in order that a man who has served the institution with distinguished success for a number of years might be made eligible, not for appointment, but for Civil Service examination; that he might come in with others on the same level and for the same tests. Such a candidate surely has an advantage because of superior prac-

tical fitness gained through actual experience in the sanatorium treatment of tuberculosis. Should not the specialist in pulmonary tuberculosis receive preference over the general practitioner or those unfamiliar with the disease through other special practice?

As a truthful statement of our present situation with relation to the selection of a Superintendent for the Ray Brook Hospital the following facts are presented: That in February, 1907, Dr. Melvin P. Burnham presented his resignation as Superintendent of Ray Brook to take effect August 1, 1907, in order that he could assume charge of another sanatorium at Los Angeles, Cal., in the autumn under better financial circumstances. The State Civil Service Commission, without any consultation with the Board of Trustees of the Ray Brook Hospital as to their notions of the attainments necessary for the Superintendency at Ray Brook, ordered an examination during early May of 1907. This examination was entirely written. The questions found their origin either in the mind of the lay chief examiner of the Civil Service Commission or in the mind of some special medical examiner having no actual experience in tuberculosis. The questions in the written examination relating to professional capacity were chiefly laboratory and library, and related to problems not well established, particularly with relation to the opsonic index and the action of sera, all of which were largely problematical and have no sufficient support through the best authorities on tuberculosis. So large a proportion of the examination was given to the purely theoretical side of the question and the disputed problems of pathology that only persons who had taken a library course of instruction or who had "read" for the examination could very well answer. Any candidate familiar with any good text-book on physical diagnosis could doubtless answer the questions presented with greater fullness than could men of prolonged actual practical experience at the bedside. The proposition that physical diagnosis may be learned from reading text-books is so indefensible that it requires no further discussion here. The niceties of diagnosis in pulmonary tuberculosis, particularly in its earliest stages, are not to be learned by reading text-books, but can only be attained through prolonged, varied, and practical experience under the direction of very skillful teachers.

The men who passed the examination qualifying them for the appointment of Superintendent at Ray Brook were men who during their entire life had had no practical experience in the diagnosis and sanatorium treatment of tuberculosis, except in an incidental way common to all general practitioners. Of the entire list from which the Board of Trustees could make an appointment there were not more than two men, so far as we were able to determine, who had had any actual or prolonged practical experience in the treatment of the disease, and they stood rather low on the list. Of the three candidates presented by the Civil Service Commission to the Board of Trustees of Ray Brook for the selection of Superintendent the following situation was presented: That two of them, practically from the time of their graduation until the time of their passage of this examination for the Superintendency at Ray Brook, had been continuously associated with the public service in State hospitals for the insane and had received no special training in tuberculosis. The third candidate on the list had been a contract surgeon in the United States Army from the time of the Spanish-American war until the time of examination and had served in several posts throughout the country, none of which were associated with a tuberculosis hospital. If we were to follow absolutely the directions of the Civil Service law we would be compelled to take one of these three men, temporarily at least, as the Superintendent, and under the rules of the Civil Service Commission could not secure a single additional name unless declinations from the other candidates could be obtained.

I ask you frankly if the Board of Trustees of the Ray Brook Hospital can afford to appoint as the Superintendent of that institution any physician who is not especially experienced and skillful in the diagnosis and sanatorium treatment of pulmonary tuberculosis. I believe that you fail to understand that in the State of New York there are a large number of men who seek to improve their position financially and socially largely through their capacity to prepare and to successfully pass Civil Service examinations as now conducted in New York State. I have no objection to a man improving his position through increase of salary if it present with it a satisfactory capacity, but I must submit that men trained in insane hospitals and men trained for the service of the United States Army or the Marine Corps of the United States service present no conclusive evidence that they should be made superintendents of tuberculosis hospitals.

None of the group of three men presented by the Civil Service Commission of the State of New York to the Board of Trustees of the Ray Brook Hospital have ever previously taken sufficient interest in the study of tuberculosis to become associated with any of the State or national societies for the study of that disease and none of their names are on the roster of the third annual meeting of the National Association for the Study and Prevention of Tuberculosis. The factor of deep personal interest, of an investigating enthusiasm, and a disposition to meet and exchange experiences in societies and otherwise with other men interested in the same subject are indications of virility in a superintendent. The Ray Brook Hospital does not want now, has never wanted, and so long as I am a trustee of that institution I am of the opinion that it will never elect, a superintendent who has not established at least some little reputation for himself in a practical kind of a way in the sanatorium treatment of tuberculosis, and who has not, besides, an interest in the disease and its study which is not measured by salary and perquisites. This situation may be entirely too ideal for a Civil Service examination.

The MEDICAL RECORD can do more for the Ray Brook Hospital than it has done when it furnishes the widest publicity possible by its large circulation to the fact that the position of Superintendent of the Ray Brook Hospital is now vacant and that the Board of Trustees of that institution, I am sure without a single exception, are seeking to secure for that position a person having the widest knowledge of tuberculosis and its sanatorium treatment, and that political influences will not be a factor in securing an appointment to that position. In no other department, of management, of administration, of engineering, or of nursing, has any conflict occurred with the Civil Service Commission, and every salaried appointment made at Ray Brook is a Civil Service appointment, either with or without examination. I think that there is no institution within the State of New York that has fewer exceptions to the provisions of the general Civil Service law than has Ray Brook, and, moreover, the Board of Trustees are not disposed to ask of the Civil Service Commission any exemption from its provisions.

W. G. MACDONALD, M.D.,
Member Board of Trustees, N. Y. S. Hospital for Treatment of Incipient Pulmonary Tuberculosis at Ray Brook.

THE MELODY CURE OF STUTTERING.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR—In one of your recent issues Dr. E. W. Scripture writes interestingly on the treatment of stuttering and stammering, in which he claims to effect happy results with the so-called "melody cure." The tone of this article conveys to the reader's mind its author's originality in discovering this euphonious method of treating this distressing affection. To quote from his paper: * * * "This melody cure I have never read or heard of before; I stumbled on it quite by chance while trying the various other cures." Clearly an innocent claim to originality.

Not wishing to detract from the merit of Dr. Scripture's article, which is both instructive and interesting, but for his enlightenment as to the priority of the "melody cure," I submit the following from a recent issue of the *Etude*, a musical publication: "Byrd, in his collection of Psalms and Sonnets, dated 1588, amongst many trite suggestions as to the value of learning music, offers the following: 'It is a singular good remedy for a stuttering and stammering in the speech.'" Clearly, the award of priority belong to this great music master.

C. ROSENHECK, M.D.
NEW YORK.

New Zealand as a Field.—A correspondent of the *Glasgow Evening Times*, after describing the many advantages possessed by New Zealand in point of climate and prosperity, says that the country could accommodate five hundred more doctors, and supply them with a clear income of £400 to £500 a year. In the large towns incomes running up to £2,000 a year are not out of the way, but the ordinary country practitioner is wanted in great numbers.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HOSPITAL FUND—QUEEN VICTORIA'S NURSES' INSTITUTE—MYOMECTOMY DURING PREGNANCY—CONFERENCE ON INFANTILE MORTALITY—LOW COSTS IN A DEFENCE ACTION—HOSPITAL PATIENTS' PREJUDICES—DR. HALL-EDWARDS.

London, March 27, 1908.

The annual meeting of the King's Hospital Fund was presided over by the Prince of Wales as president. The reports showed the receipts for the year were £484,060 10s. 9d., but a large part of this was on capital account. The amount distributed was £121,000, in addition to which amalgamation grants of £2,750 falling due were paid. The League of Mercy contributed £18,000, the same as last year. The fund was incorporated by an act of Parliament which came into force July 26, 1907, and the Council says it has so far worked satisfactorily. The amalgamation of orthopedic hospitals is now complete: efforts to unite the throat and ear hospitals are still going on. The Prince, in moving the adoption of the report, said that on the advice of the executive committee he had decided to appoint a committee to inquire into the system prevailing in the London voluntary hospitals regarding the admission of out-patients, and he hoped the labor involved would to some extent be lightened by the work of the Royal Commission on the Poor Laws. So far as this may deal with medical relief, the evidence and conclusions must be of importance in connection with the fund's inquiry, which will therefore be postponed until the commission has reported. The Prince also announced that the growth of London had been so great during the eleven years since this fund was instituted that its operations have been extended from a radius of seven to nine miles from Charing Cross. Further, it was proposed this year to consider the claims of consumption sanatoriums in the country, which take a large proportion of their patients from London, and such institutions are better in the country than in London or its suburbs.

An appeal on behalf of Queen Victoria's Jubilee Institute was issued on Monday. There are now 1,116 nurses trained in district nursing at the cost of the Institute working among the poor throughout the country, and the expenses exceed the income by £3,000. There are fifty-three places where associations are organized and waiting for the nurses to be sent. The aim of the executive committee is that "not a wild mountain glen, not a sad city slum, not a village in the Kingdom, shall be without its health missioner to the poor." Queen Alexandra countenances the appeal and Miss Nightingale has sent a message in its behalf from her sick bed.

At the meeting of the Obstetrical and Gynecological Section of the Royal Society of Medicine Dr. Walter Swayne read an account of two cases of myomectomy during pregnancy on which he had operated. In one a pedunculated fibroid the size of an adult head was removed from the fundus. A smaller senile one behind and below the other was enucleated. The pregnancy had not been interrupted two months later, when last seen. In the second case a fibroid was growing from the right cornu and had undergone rotation so that it lay on the left. It was untwisted and enucleated. Pregnancy interrupted a month after leaving hospital. Dr. Swayne thought fibroids should be removed if they caused pain, pressure symptoms, axial rotation of uterus, or signs of twisted pedicle.

Dr. J. H. Dauber then communicated a case of a much more formidable kind in a woman of 31, married three months, which had been previously diagnosed as pregnancy complicated with a tumor. It was obvious that a tumor occupied the whole of the pelvis and the abdomen was as large as in pregnancy at nine months. On opening the abdomen a large irregular solid tumor was exposed, lying to the left and extending from deep in the pelvis to the arch of the diaphragm. It was fixed and retroperitoneal throughout. Behind it in the right iliac fossa lay the pregnant uterus, adherent by the cervix, which was greatly lengthened. Many adhesions of intestine; in pulling them off a rent was caused in the capsule of the tumor and as it was obvious it would shell out it was enucleated, except the pedicle, which was as large as a small wrist and was attached to the cervix. The hemorrhage was very great and impossible to control, so that amputation of the uterus supravaginally was done to save life. Dr. Dauber greatly regretted sacrificing the uterus, but it seemed necessary, and Dr. Mansell-Moullin, who was present, concurred. The fact that the tumor was beneath the broad ligament and had burrowed up behind the peritoneum as far as the left kidney created extreme difficulty, but the patient did remarkably well.

In the subsequent discussion, if the term may be applied to a series of similar opinions, the generally accepted view was reinforced that unless for definite and very serious indications fibroids complicating pregnancy are best let alone.

Dr. Herbert Spencer, president, without criticising the three cases, held that myomectomy, though occasionally urgently required for very large or impacted or rotated tumors was only rarely necessary, and as the cases related showed, was attended with considerable risk. The operation should be postponed if possible until the child was viable.

Dr. Champneys followed in the same sense. He had long experience of the complication of pregnancy with fibroids, and though in some cases he had been obliged to resort to exceptional measures, such as cesarean section, he had known many where some alarm had been felt by the patients or their advisers, but the pregnancy had gone on safely and other children had subsequently been born. He thought interference was required in extremely rare cases.

Dr. Herman concurred, but said some statistics mentioned gave too high a mortality. He related a case in which he had enucleated the fibroid attached to a pregnant uterus and the patient was delivered of a full-term child six months afterwards.

Dr. Amand Routh had collected statistics which indicated that by modern methods the danger to life was much less than absolute figures showed—in fact, the risk was not so much during labor as from subsequent sepsis. If the endometrium became infected, a submucous or intramural fibroid would almost certainly become so. Abortion did not often occur when fibroids were present, though labor might ensue a few months before term. No operation should be undertaken unless absolutely essential until the child was viable. He had only twice done cesarean hysterectomy and in both cases near full term. He had often found fibroids blocking the pelvis in the early months, but they always underwent flattening and softening—were suddenly or gradually displaced, sometimes as late as the onset of labor, which occurred spontaneously without assistance.

Dr. Eden agreed with the previous speakers as to the rarity of the complication and its comparative unimportance.

Dr. Arthur Giles said generalities were of no value. It was beside the mark to say fibroids were usually unimportant or usually dangerous. Fundal fibroids might make no difference to pregnancy and labor, but cervical fibroids impacted in the pelvis were in another category. He mentioned a case in which he removed the fibroid from the broad ligament and had great difficulty to control the hemorrhage, which recurred later, and he had to remove the uterus as Dr. Dauber had to do.

The conference on infantile mortality was opened on Monday, when Mr. John Burns as president gave an address. He congratulated the delegates upon the progress made during the past year. He advocated natural milk for infants, good "mothering" being a necessity for the young. This, he said, was more necessary than ever, and a woman should not be at factory work for six months before or as long after the birth of a child. He has received two or three deputations respecting the contemplated bill on milk, and to one of them he said he hoped the supply of the country would be placed by it on a much better footing.

On Tuesday the conference was largely attended by medical, sanitary, and other representative officials and persons interested. Dr. C. W. Saleeby read a paper attributing the cardinal difficulty against which the conference had to meet was the lapse of instinctive aptitude on the part of the human mother, who now possessed only instinctive love and uninstructed intelligence.

Miss A. Ravenhill read a paper advocating a prolongation of elementary education in order that the girls might be trained, not only in the duties, but in the functions of womanhood, so that they should acquire a higher conception of the dignity and vital responsibility of parenthood. As to which, a mother says it is curious how single women all think they can instruct the married. Miss Lanetti, considering the relationship of feeble-mindedness, illegitimacy, and infantile mortality, was strongly of opinion that the detention of persons unfit for parentage was absolutely necessary.

Councillor Anderson referred the unemployment problem to infantile mortality, or, as he went on to explain, to the "struggle of infancy," which handicapped

many in their future, and these, he said, perpetuated a weaker generation than themselves.

The deliberations of the conference were brought to a conclusion on Wednesday, when a series of more or less important resolutions were adopted, among which those concerning the education of girls, the milk supply, and the sale of foods and drugs were perhaps the most important. What may be the result of the recommendations made to Parliament is doubtful, but it is perhaps well that so many interested advocates of different opinions should have met together to consider them. As to foods and drugs offered or sold for infants, it was resolved that they should be certified by a Government analyst as noninjurious, and that each packet should have the analysis printed on it.

A fund is being raised to meet the law costs incurred by Drs. Thomas and Skyme in defending an action for malpractice. The appeal is signed by so many professors, teachers, and surgeons that it seems as if those best able to judge are practically unanimous. The case was tried in December, 1906, the patient claiming above £2,214 damages. The jury could not agree and in November, 1906, a second trial resulted in a verdict for £100. This leaves the defendants liable to the costs of both trials, amounting to over £4,000, of which the Defense Union has paid £900. The sympathy of the profession seems universal. Canadian and American surgeons have expressed strong opinions on the case, so that you probably know all about it. Does it not seem monstrous that the costs of defending oneself from such a charge should amount to a small fortune?

The difficulties of dealing with some hospital patients are illustrated in a statement by Dr. Robertson, physician to the Ventnor Consumption Hospital, at the annual meeting held in London yesterday. When the fresh-air system was first tried the mother of a patient in a room with an open window complained not only to the governors but to Queen Victoria, and Her Majesty sent her own physician to inquire into the matter. Now, said Dr. Robertson, there is not a closed window in the hospital. So when graduated work was first attempted in the grounds they asked for payment. Now they are most anxious to be employed, for they take it as a sign that they are improving. The chairman said 897 patients had been treated during the year with beneficial results at a cost of £12,786, but the income was only obtained with difficulty.

I am glad to report that a civil list pension of £120 has been granted to Dr. Hall-Edwards, in recognition of his services. It is sad, however, to have to add that the *x*-rays have injured the other hand and that expert advice is that all four of its fingers must be amputated, though it is hoped to save the thumb. Of course, the pension named does not render unnecessary the fund which is being otherwise raised.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PHILIPPINE ISLANDS MEDICAL ASSOCIATION—RAPPROCHEMENT OF FILIPINO AND AMERICAN PRACTITIONERS—RELATION OF BACTERIAL SYMBIOSIS TO ANIMAL PARASITISM—PROGRAM OF MEETINGS—FOREIGN DELEGATES.

MANILA, P. I., February 27, 1908.

THE fifth annual meeting of the Philippine Islands Medical Association was opened yesterday afternoon under most promising conditions in one of the lecture rooms of the Philippine Medical School. The attendance exceeded even that of last year, and much interest and enthusiasm were plainly evident. Delegates are present from Ceylon, Siam, Straits Settlement, Indo-China, Hong Kong, China and Japan, making a total of nine foreign representatives. The local medical men were also more numerously represented than in former years. This is largely due to the constant increase in membership of the association, the growth of which has been constant since its organization, so that it may now be said to be thoroughly representative of the medical profession in the islands.

Another encouraging feature is the fact that each year the Filipino physicians are showing more and more interest in American methods and American medicine, and seem most anxious to become more proficient in them. On the other hand, the American medical men, through their more intimate association with their Filipino brethren, are learning much as to their habits of thought, and also profit by sharing the experience of those who have been acquainted with local conditions all their lives. The best of feeling apparently prevails, and much will, no doubt, be accomplished by this meeting in furthering the advancement of medicine in the Philippine Islands.

Governor-General Smith made a brief opening address in which he welcomed the foreign delegates to the Philippines, and assured the members of the association that the same support which the government has heretofore extended toward furthering the advancement of the science and art of medicine in the islands would be given in the future.

The Mayor of the city, Mr. Roxas, then followed with a brief address, in which he emphasized the importance to the Philippine Islands of gatherings of this nature, and thought much good must inevitably result from the interchange of ideas that would take place with the medical men, not only from the different islands of the group, but also from many other parts of the Orient.

He was followed by Dr. W. E. Musgrave, who delivered the President's address, entitled "The Influence of Bacterial Symbiosis upon the Biology and Pathogenesis of Animal Parasites." Dr. Musgrave in his address placed himself upon the side of that school which now seems to be slowly forming which believes that microorganisms, when surrounded by adverse conditions, also develop resisting powers much in the same way as the human organism now develops immunizing powers against the bacterial invader. He concerned himself, however, principally in calling attention to the large field which lies in the direction of the further study of symbiosis, and invited attention to the work in recent years done in this direction, as well as to his own work, which was done several years ago, in which he showed that amebæ could not be cultivated alone, yet this became a simple matter when they were grown in connection with the typhoid or colon organisms.

The afternoon session was followed by a reception by the Manila Medical Society to delegates and members of the Philippine Islands Medical Association at the Elks Club at 9 P. M. The reception was a social success, many families and friends of the guests being present. The receiving line was formed by the Governor-General and Mrs. Smith, the Commanding General of the Philippines Division of the United States Army, and Miss Weston, Mrs. Worcester, Mrs. Leas and Drs. Freer and Musgrave.

The work of the meeting will commence with a clinic and luncheon at the Division Hospital at 10.30 A. M., and this will be followed by a scientific session which commences at 3 P. M. in one of the lecture rooms of the Philippine Medical School. This evening a dinner will be given to the delegates and officers of the Philippine Medical Association. At 10:30 A.M., on the 28th, the second scientific session will be held, which will consist mainly of a series of papers upon cholera and more particularly with regard to some new developments in connection with this disease. In the evening a dinner will be given by the Governor-General in honor of the foreign delegates.

On the 29th two scientific sessions will be held, one at 10 A. M. and the other at 3 P. M. Among other things time between sessions will be taken up in discussing the advisability of forming a far Eastern Medical Association, which would include the medical men of the entire Orient. Time has also been set aside for visiting the laboratories of the Bureau of Science, the prison, insane, leper, cholera and smallpox hospitals of the Bureau of Health.

On the afternoon of March 1, in response to an invitation from the Navy Medical Corps, a trip will be made to Cavite for the purpose of visiting the Cañacao Hospital. On the morning of March 2 the corner stone of the new $400,000 General Hospital will be laid. In the afternoon a trip, by invitation of the Army Medical Corps, will be made to Fort William McKinley.

An excellent pathological exhibit in which the specimens are changed before each session is conducted at the medical school.

The different countries are represented as follows: Ceylon by Sir Allan Perry, the Honorable Principal Medical Officer of Ceylon; Straits Settlements by Dr. R. D. Keith, Physiologist, Straits and Federated Malay States Medical School, and by Dr. H. Fraser, Institute for Medical Research, Kuala Lumpur; Imperial Chinese Majesty's Government by Cheng Hao; Colony of Hong Kong by Dr. Francis Clark, Medical Officer of Health; Indo-China by Dr. J. J. Vassal, Institute Pasteur Nhatrang, Annam; the British Royal Army Medical Corps by Surgeon-Lieutenant Ryley, and Japan by Professor Taichi Kitajima, M.D., Infectious Disease Institute, Tokio.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 2, 1908.

Remarks Upon Intussusception with a Suggestion for a New Method of Operation Upon Cases in which Reduction Is Not Possible.—E. A. Codman tabulates some 27 cases of this surgical condition seen in the Massachusetts General Hospital in the course of ten years, the number being 27, of which 10 were in infants under one year. The histories of several of the most important cases are given in full. The author makes a plea for mesenteric ligation, the method of employing which, he describes in full. He lays down the following general rules in regard to treatment: (1) All cases in infants and children in which the diagnosis can be made and which are not already very feeble, should be given one forcible oil enema under an anesthetic on the operating table. This should be followed by laparotomy whether the tumor disappears or not. (2) Before using efforts at reduction forcible enough to cause increased shock, the surgeon should, *if he does decide on it,* make up his mind to carry out reduction up to the limit of the patient's strength. (3) If reduction is considered too doubtful, resection with double enterostomy is the choice when (*a*) the mass is wholly composed of small intestine; (*b*) when it is wholly composed of large intestine and the mechanical conditions make resection easy. (4) If reduction is abandoned and the mass is wholly composed of large intestine and resection cannot readily be performed, excision of the intussusceptum is indicated by Barker's or Mikulicz's method. (3) In irreducible cases in which the small intestine is invaginated into the large, simple enterostomy without resection and resection of the mass should be abandoned and replaced by ligation of the impacted mesentery and enterostomy. (6) In infants where there is already evidence of severe exhaustion, ligation and enterostomy could probably be done very rapidly and with less operative shock than even a successful reduction, provided the operator from the beginning abandoned any idea of reduction. The essential object of the operation which is here suggested is to produce gangrene of the intussusceptum in a convenient manner so that within a few days enough softening of the constricted portion will have taken place to allow of its ready reduction by gentle traction. When the arterial supply is cut off it cannot be long before the blood and edema in the intussusceptum will be squeezed out by the peristalsis of the intussuscipiens, leaving the submucosa still strong enough to stand a gentle pull. The suggestion is offered particularly for desperate cases to replace resection and hopeless effort at reduction. It would be easier, quicker, and produce less shock than any other form of operation.

Anomalous Folds in the Nasopharynx.—Two unusual cases have recently come under the observation of J. P. Clark. In both instances smooth folds were attached to the Eustachian prominences and draped up like portieres to the vault of the pharynx. One patient came under observation for tonsils and adenoids and these were removed. He was also deaf and the operation was followed by great improvement in hearing, but the folds were left undisturbed. In a second similar case occurring in a young adult, a small piece of the folds was punched out and submitted to the microscope but it revealed only the structure of normal pharyngeal mucosa. Clark has found nothing in the textbooks bearing on this anomaly. The folds were situated between the auditory tube and the fossæ of Rosenmueller and were consequently in the position of the arch which lies between the first two gill clefts of the embryo (counting the spiracular cleft first). In the cases presented, the folds may be only adventitious developments of mucous membrane.

New York Medical Journal, April 4, 1908.

Lactacid Milk in Infant Feeding.—C. E. Carter offers a general consideration of this subject and presents the following summary: (1) Lactacid milk is obtained from clean, fresh cows' milk, fermented by the lactic bacillus, isolated by Cohendy in 1903, and which he describes as "not growing under 35° F. nor above 63° F." The degree of acidity is limited by the time allowed for the activity of the bacilli. (2) Buttermilk feeding and lactacid milk feeding are absolutely distinct. The former affords an uncertain and temporary expedient always, and being a spontaneously sour milk contains, besides the lactic ferments, generally yeasts which produce alcohol. (3) In infant feeding the frequent desideratum of high proteid percentages may be found not only possible, but also safe, with lactacid modification of milk. (4) The digestive enzymes of natural milk are not killed as in the unnatural processes of sterilization or even in Pasteurization, but are augmented by the *Bacillus bulgaricus*. (5) Lactacid milk is logically indicated in children: *a*, In difficult feeding cases; *b*, in fermentative diarrheas; *c*, in specific enteric infections of typhoid or tuberculous bacilli. (6) From the extremes of the scientist and the enthusiast, from Herter and from Metchnikoff, come corroborative evidence that lactic acid inhibits intestinal putrefaction. (7) Promulgation of the general desirability of undiluted lactacid milk as a beverage can but lessen the ills that flesh is heir to, even if it cannot accomplish, as Metchnikoff hopes, the prolongation of man's alloted span. (8) The writer presents this as a preliminary communication, and will later submit a series of results obtained in indicated cases of lactacid milk feeding.

Carious Teeth in the Tenement Population of New York City.—H. Emerson gives the result of examining 2,301 tenement house children with reference to their dental condition. Of this number 1,478 were between ten and fifteen years old; 18.8 per cent. of the latter had normal teeth while 81.2 per cent. were defective in this respect. Each defective averaged 4.7 bad teeth. Of the 634 examined over fifteen years of age, only 3 per cent. had no decayed teeth while 97 per cent. had an average of 6.5 decayed teeth per person. The author found that the use of the tooth brush and even mouth rinsing were conspicuous by their absence. The author has no figures to prove that mouth infection involving the fauces and tonsils are more common in individuals with many carious teeth, but the condition of the soft tissues which come in contact with carious teeth, at the gum margin or upon the buccal or lingual mucous membranes, certainly suggests that there is a pretty constant source of septic or putrefactive bacteria in the crypts of the decayed teeth. He further believes that proper oral hygiene will check the prevalence and increasing incidence of respiratory disease and that prophylaxis and treatment of decayed teeth should be undertaken on a comprehensive scale as a public necessity.

Chronic Alcoholism.—G. E. Pettey discusses what can be done and what cannot be done by treatment. He classifies habitués of alcohol as regular drinkers and periodical drinkers, each class having several subdivisions. Treatment of all classes should begin with the elimination of all waste products which the effects of alcohol have caused the system to retain. Bowels, kidneys, and skin should all be called on. Then come on the various electric treatments, vapor showers and other baths, suggestive physical training, discipline, etc., for those patients of the more promising class. Another class will need special treatment for the relief of the stomach catarrh which is so troublesome in alcoholic cases. Treatment must be kept up until the patient is able to enjoy and assimilate three good meals daily. Most of these chronic cases can be best cared for in an institution where better disciplinary environment can be maintained. The author admits that the wide range of temperament found in this class of patients but believes that as large a percentage of permanent cures is possible as with any other serious ailment. The physical man must be renovated and every bodily function restored to normal activity while the mental bias favorable to the use of alcoholic liquors must be eradicated.

Journal of the American Medical Association, April 4, 1908.

The Treatment of Iritis.—E. C. Ellett considers atropine the most efficient drug for dilating the pupil in iritis; the standard solution of four grains to the ounce may need to be modified. If adhesions have formed it may be advisable to increase the strength up to eight grains for a few instillations to break up the adhesions, and, on the other hand, with children and susceptible subjects, a weaker solution than the standard may be expedient. Usually, with the patient at rest and surroundings favorable, four instillations in twenty-four hours will suffice, and when full dilatation has been secured, the frequency can be diminished till the minimum dose that will keep up the mydriasis is reached; this dose is then continued until the eye is free from redness. If the drug fails to dilate the pupil fully, Ellett favors the use of one drop of cocaine solution preceding the atropine to get the combined effect of the drugs. Moist heat, being more energetic, is preferable to dry heat in aiding to maintain mydriasis, though both are useful. The local abstraction of blood is also an aid. Protection from light and rest to the eye are valuable adjuvants to other measures in treatment of iritis. Every patient with iritis would be better for confinement to bed till convalescence is established in Ellett's opinion. So-called "atropine catarrh," he is satisfied, is only the result of infection from dirty solutions and droppers. Applying the solutions warm by rinsing out the syringe with hot water before drawing up the solution insures a clean dropper and less irritation to the eye. The above measures tend to relieve pain, and while pain persists, improvement is not imminent. Dionin, though sometimes effective, is, in Ellett's experience, less

reliable for relieving pain than moist heat. In traumatic cases, with threatened or feared suppuration, cold applications seem to be of the most value, and should be continued as long as needed at all. Anodynes are often necessary internally and opium is most effective, but unpleasant on account of the systemic disturbances to which it gives rise. Counterirritants may sometimes be useful, and blood letting by leeches aids the mydriasis as well as relieving the pain. Sometimes the pain is due to an increase of tension, or the latter may occur without increase of pain. Hot applications may relieve this, but most often fail, and if the tendency to adhesions is not marked, we may use a myotic, alternating with the mydriatic, or at least dilating the pupil once in twenty-four hours. If this fails, paracentesis may be done, and Ellett would prefer to do this early, and to repeat it if necessary, continuing the mydriatic. Constitutional treatment is essential and includes attention to every constitutional condition that can in any way retard the cure or interfere with the action of remedies. Aside from its relation to cause, internal treatment is of importance and mercury and the salicylates are of great value in other forms than the syphilitic and rheumatic. Ellett has not had a very favorable impression of the value of the iodides except in chronic cases or in cases associated with choroiditis and running a slow course; nor does he find sweats so effective as in choroiditis and general uveitis. Burnham's "combined method" of the use of mercury, iodide, and pilocarpine is considered by him well worthy of a trial.

Alimentary Intoxication.—W. J. Butler discusses the condition called alimentary intoxication by Finkelstein, the clinical picture of which is better known under the names enterocolonic catarrh, milk poisoning, bowel infection, etc., and in its severer form, cholera morbus. It occurs in children who have been slightly abnormal, as shown by the temperature and weight charts, but without striking morbid symptoms. It is always preceded by a qualitative or quantitative increase or change of diet and the onset of intoxication is announced by marked nervous symptoms. After a varying period of irritability, the infant is seized with convulsions followed by stupor or coma, or it becomes apathetic, drowsy, and even comatose. The temperature usually rises sharply, but not always. The stools are often more frequent, but may seem normal at the beginning of the attack. There is considerable depression, and, in the severer cases, marked collapse with low blood pressure and livid skin. Before, or with the rise of temperature there is a sudden decline in the weight curve, the breathing is accelerated, rather deep, and may be misinterpreted as a pulmonary symptom. A striking feature at the height of intoxication is the alimentary glycosuria, dependent on lactose and galactose, and due to their absorption and failure to undergo oxidation. Albuminuria and cylindruria may coexist. A leucocytosis, not exceeding 30,000 is always seen during the acute stage. The physiognomy is markedly different from that of the normal infant. The symptoms vary with the case, in some being typical, in others, one or other symptoms predominating. Finkelstein recognizes several forms; the choleraic with great loss of weight and collapse, and without marked cerebrospinal symptoms; the hydrocephaloid forms simulating a tuberculous meningitis; the soporose form, and asthma dyspepticum, in which the peculiar breathing is the most marked symptom. The incipient dyspeptic stage may develop into a chronic intoxication, a marasmus, instead of the acute intoxication described. Butler reviews the arguments for and against the bacterial pathology of the disorder and concludes that the cause must be sought, not in bacterial infection or food decomposition, not in toxins supposed to be contained in milk, as this condition may occur with the most careful preparation of food, but in an intolerable quota of nourishment, either quantitatively, qualitatively, or both supplied to an infant already suffering from nutritional disturbance, resulting in an abnormal destiny of the nourishment in intermediary metabolism. The presence of glycosuria at the height of the intoxication would indicate some grave perversion of metabolism. The indications for treatment consist in combating the collapse, cutting short the intoxication, and bringing the child back to a diet commensurate with its caloric requirements. The first indication can be met by hypodermoclysis of salt solution, using from 50 to 100 c.c., and repeating when deemed necessary. The second is met by entire withdrawal of food and administration of water only for twenty-four hours. With the subsidence of all symptoms, he begins feeding with teaspoonful dose five times a day of centrifugated breast milk if possible, or an equal quantity of buttermilk, adding neither sugar nor meal. If this is not available, fat-free milk may be used. As a diluent, water and a thin cereal gruel may be used. After twenty-four hours, if this is well tolerated, and no sign of the intoxication reappear, the milk may be increased to two teaspoonfuls, which after two or three days, all going well, may be again doubled, and so on till the diet (fat-free in artificially fed infants) is reached that will meet the caloric needs, having added in the meantime, with the increased tolerance of the buttermilk when employd, 30 grams of sugar, preferably maltose, and 15 grams of flour to each liter of buttermilk while boiling. In case of breast-fed infants, after four or five days' feeding carefully with centrifugated breast milk, the child may be returned to the breast, the amount of nursing being carefully controlled. The buttermilk diet should not be kept up over six weeks, after which whole milk dilutions will be required. Slight relapses are liable to occur during the treatment if the food toleration limit is passed. It is best to go slow, allowing forty-eight hours for judging the effect of each food increase. Cathartics and intestinal antiseptics are not needed unless there is constipation, as is sometimes the case in the soporose form, when a laxative is indicated.

Scarlet Fever Epidemic from Milk.—H. B. Hemenway gives the history of an epidemic of scarlet fever that occurred in the city of Evanston, near Chicago, in the winter of 1906-7. He describes the conditions and shows, apparently conclusively, the connection between the extension of the disease and the use of milk from a certain source of supply. This source had been under suspicion on account of a number of cases of scarlatina occurring during the previous summer and fall, but the real epidemic began early in January, 1907, and was at its height between the fourteenth and nineteenth of the month. Whole families were attacked in a day and a notable proportion of the patients were adults. Cases occurred also in the adjoining portion of the city of Chicago and in a village immediately north of Evanston, as well as in a western suburb of Chicago about this same time, in all of which regions a considerable portion of the milk was supplied from the same source. Nearly all the cases in Evanston occurred in users of this milk and the same was true in Wilmette and Oak Park, where it was also supplied from the same source. On the other hand, in the adjoining village of Winnetka, which did not receive milk from this source there was but one case of scarlet fever, and that was clearly traced to contagion. In short the distribution of the cases of scarlet fever showed throughout a close relation to this particular milk supply which went to about one-seventh of the milk consumers in the territory. There was a sudden fall in the reported new cases when the supply from this source was discontinued by the orders of the local health commissioner, while they continued to increase in Chicago where the milk refused at Evanston was delivered. Few cases were recognized as due to contagion except those traced back to users of the suspected milk, though this phase of the matter was carefully investigated. The epidemic in Chicago reached its height a little later than at Evanston, but followed a similar course, declining a little less suddenly after the discontinuance of the milk supply from the suspected locality. Investigation by the Evanston health authorities revealed a number of cases of scarlet fever occurring in January in the locality from which the milk was sent, some of them in families supplying the milk or including employees of the milk company. The milk was bottled on the spot and the chances of its infection in transit need hardly be seriously considered. Hemenway gives the credit of checking the epidemic to the hearth department of Evanston, which first took the matter up and traced the infection to its source. He criticises certain other officials for their delay in this matter and points out the necessity for a thorough organization of health officials, local, state and national, so that no possible question of authority can delay investigation and action.

The Lancet, March 28, 1908.

Meralgia Paræsthetica Successfully Treated with the Constant Current.—E. R. Morton gives brief notes of three cases of this malady which is also known as Bernhardt's affection of sensibility and relates to the distribution of the external cutaneous nerve in the thigh. Its main feature is a feeling of numbness of woodenness or pain on the front or outer side of the thigh according to the distribution of the nerve mentioned. Sometimes there is a feeling as if the skin was very tightly stretched over the area. The superficial course of the nerve and the way in which it pierces the fascia lata are predisposing causes for its involvement. The lesion is probably a localized perineuritis with associated interstitial and parenchymatous changes in the nerve. External trauma will account for most cases, although at times the nerve may be come nipped in occupations calling for extra tension on the fascia at this point. The author notes that the use of the faradic brush in this affection has been disappointing but that much satisfaction follows the use of the constant current. He places the indifferent (negative) electrode over the lumbosacral region while the positive is applied over

the affected area and especially over the site of emergence of the nerve. No one area receives the current for more than two or three minutes at a time. The current varies from 30 to 50 ma. In his hands this mode of electrotherapeutics has given most satisfactory results.

Modern Methods of Treating Infective Conditions of the Throat.—Meredith Young has undertaken a series of experiments to observe the respective values of gargling, douching, swabbing, use of trochees, etc., in combating septic conditions in the mouth. He has made cultures before and after the employment of these various methods from throats seen in connection with scarlet fever, diphtheria, "hospital sore-throat," etc. His results go to show that for throat disinfection gargling possesses no advantages but rather several disadvantages. It is merely a flushing process at best and sterile water is doubtless as efficient as are many of the gargles used. Douching properly done is useful but is hardly adapted for anything except hospital service owing to the difficulty of performing it and the dangers of it when improperly done. Spraying is little better than gargling. Gratifying results were obtained in Young's observations by the use of medicated lozenges. The best method proved to be swabbing. The author says that to secure the best results with this method the patient should be placed with the head well back over a pillow in pretty much the same position as for removal of adenoids so as to prevent any liquid from the swab going into the larynx. The swabs should be nearly as large as a walnut and can be made of absorbent cotton or wool securely fastened in an ordinary sponge holder. They should be firmly and rapidly passed over the fauces with a rotary motion and if possible thrust up into the nasopharynx, at least three or four swabs being used at each attempt. A very useful combination for using on the swab is the one so common in otological practice, boric acid one ounce, rectified spirits two and one half ounces, and pure glycerine eight ounces. After swabbing the fauces once with this and then with sterile water the bacterial flora of the anterior pillars was reduced to 25 total colonies and there was an entire absence of staphylococci and streptococci.

The Pathology of Acid Intoxication.—This topic is considered by F. A. Bainbridge in the Arris and Gale Lecture for 1908. He regards acidosis rather as a phase of metabolism than as a separate pathological entity. There is a distinction between acidosis and acid intoxication. The essential feature of the former is the occurrence of certain organic acids in abnormal amount in the blood and urine. The most important of these are lactic and β-oxybutyric and their estimation in the urine furnishes the most accurate index of measuring the intensity of the acidosis. The term acid intoxication should be limited to those cases in which toxic symptoms referable to the organic acids make their appearance. Acidosis may be accompanied by diminution in alkalinity of the blood, but the latter remains as a rule remarkably constant. Normal alkalinity may coexist with a considerable degree of acidosis. Neither the total amount of ammonia in the urine nor the proportion of the total nitrogen excreted as ammonia necessarily correspond with the degree of acidosis. The author believes that lactic acid is never the cause of acid intoxication in man and that its appearance in the urine is either the result of excessive production by the muscles or is secondary to the failure of the liver to convert ammonia into urea. Its occurrence is not due to deficient oxidation of lactic acid by the liver. Concerning the relation of the acetone bodies to acidosis the author says that there are many facts which render it highly probable that β-oxybutyric acid is a normal metabolic product. He states that there is no definite evidence that the acidosis of diabetes differs essentially in its origin from that of carbohydrate starvation in healthy individuals except that the starving man can utilize any sugar which is formed in the body from proteid while the diabetic patient is unable so to do. From this point of view diabetes is a condition of prolonged carbohydrate starvation and the importance of the acidosis lies in the fact that it ultimately leads to acid intoxication and coma. It is well known that in starvation even a severe acidosis is consistent with fair general health, and it is not uncommon for a diabetic patient to excrete for months large quantities of β-oxybutyric acid without showing any symptoms of poisoning. But it does not follow, therefore, that a prolonged acidosis is not harmful to the tissues, although their appearance may be long delayed; the grave metabolic disturbances which usher in diabetic coma probably represent the final defeat of the tissues in their struggle to eliminate the acids, which they produce, and to preserve intact their normal metabolism and chemical constitution. The onset of coma is usually preceded for a day or two and accompanied by a fall in the output of the acetone bodies, the excretion of β-oxybutyric acid may sink from 15 grams or more to as little as one gram, and the acetone and diacetic acid may be either absent or present only in traces. Some estimations of the total amount of acetone in the urine before and during coma show this very clearly and confirm the qualitative observations of others. The large excretion of β-oxybutyric acid in coma is only observed after the administration of sodium carbonate and does not seem to occur when coma takes its normal course. The decreased excretion of acetone in the breath also indicates that the production of acetone bodies is actually lessened and that the kidneys are not unable to carry out their functions. The fall in the output of sugar and nitrogen, the fall of body temperature, and the lessened intake of oxygen all point to a decline in the total metabolism. Equally characteristic features of coma are the diminished alkalinity of the blood and its diminished content of carbonic acid.

British Medical Journal, March 28, 1908.

A Case of Vomiting of Pregnancy.—The patient of J. A. Kendall was a III-para, 27 years, who began to vomit soon after conception. She was seen by the author some five or six weeks later. Nothing in the line of internal medication had any effect on her vomiting and her condition became so deplorable that after consultation it was decided to induce labor. This was done December 29, her last menstruation having ceased on September 27. A bougie was inserted and left in for twelve hours. The next day she had some hemorrhage and pain and the vomiting ceased almost at once. Pains and bleeding continued at intervals until the twenty-third day, when the uterine contents were expelled. Recovery was without incident. The author considers the interesting points about the case to be first, the immediate relief to the vomiting by the passage of the bougie and second, the long interval between the induction of labor and its termination.

Post-mortem Staining of Bone Produced by the Ante-mortem Shedding of Blood.—F. W. Jones gives some interesting facts concerning examinations of bones found in some of the old prehistoric burial grounds of Nubia. He says that the question usually demanding an answer in the archæological investigation of broken and disturbed human remains is that of the time of the infliction of the fracture; was it produced before the death and burial of the individual, or was it caused by grave plunderers after the interment of the body? It is in such cases as this that the diagnostic value of blood staining of bone is so well demonstrated, for in disturbed burials all traces of circumstantial evidence of ante-mortem wounding may easily be absent. The diagnostic differences between the appearance of fractures inflicted before death and those inflicted after death may be very slight indeed; and in dealing with large quantities of disturbed and broken bones these slight differences are easily overlooked. The element of doubt in such cases is generally cleared up by the discovery of the dark-red stains of blood shed presumably by the act of wounding. The stains may be limited to the fractured surfaces and then a characteristic appearance is produced for the rough fragments become deeply dyed and the recesses of the cancellous tissue show darker areas by reason of their more abundant supply of the pigment. As a rule, the staining is by no means limited to one fractured bone, but involves wide areas around the seat of injury; this is especially well marked in fractures of the cranium, where very extensive reddish stains are, as a rule, present upon the flat surfaces of the skull bones. Amongst the bones with which this survey has had to deal there are no other discolorations with which these stains may be easily confused; and even on the deeply-yellow bones that are found in bodies buried in goat skins, or bones turned brown by mummy wrappings, the ante-mortem blood stain shows vividly enough. Jones believes that some of the stained bones examined by him are over 5,000 years old.

Arthrodesis and Tendon Transplantation.—R. Jones defines arthrodesis as the artificial ankylosis of a joint with the least possible sacrifice of bone. The joint thus fixed is quite healthy, usually preternaturally mobile and the muscles which should govern it are either wholly or in part paralyzed. As applied to the lower limb the object is to make a flail joint sufficiently firm to bear body weight without yielding. The author describes the general application of arthrodesis to various clinical situations. He says that (*a*) the operation should not be performed on children under 8. (*b*) It should not be performed until the surgeon is satisfied that the muscles are paralyzed beyond hope. (*c*) The preliminary preparation of the foot by wrench and tenotome must correct all deformity. (*d*) The operation should be so planned that at its completion the bones lie in apposition to the foot, which should be placed in an overcorrected position. This is effected by the exsection of skin flaps, by the shortening of lengthened tendons, and by the removal of graduated wedges of bone.

(e) The wedge should never be taken from the tibia, lest the tibial epiphysis be injured. Splints should be applied and retained until union is pronounced to be complete, and appliances should be worn until the surgeon has evidence that the ankle can bear body weight without fear of yielding. Concerning tendon transplantation the following points are insisted on: (1) The overcorrection of deformity as a preliminary act. (2) The removal of skin flaps to secure the uninterrupted continuity of the overcorrection. (3) The direct and not angular deflection of the tendon. (4) The free tunneling in the one plane through the soft tissues. (5) The firm suturing into periosteum or bony groove. (6) The careful choice, tension, and nursing, of the transplanted tendon. (7) The maintenance of a hypercorrected position until voluntary power is assured to the tendon. (8) The deflection of body weight during walking from the reinforcing tendon. In addition to these, it may sometimes be well to shorten all the paralyzed tendons and prevent the overaction of their opponents by tenotomy.

New Ideas on Fractures.—Lucas-Championière comments on the fact that the modern use of the *x*-ray in picturing fractures and the results of treatment, constitute a certain danger for the surgeon. The public are becoming much more critical and are passing condemnatory judgments on superficial information. He says that he has for many years impressed on his students the following points: "The accurate juxtaposition of the fractured extremities of bones, in order to reproduce the normal arrangement, is a laudable object. It is only achieved in a minimal number of cases. Never tell a patient that you are going to obtain and that you have obtained this exact result. The books teach you that this is the case, but clinically the statement is false, and it will turn against you in several ways. The conditions that are necessary in order that a limb should again become functionally perfect are far from demanding this exact juxtaposition. There are a large number of conditions which are more essential and which you should be more sure of satisfying. Do not insist upon this claim." The author says that theories and mathematical considerations play only a subordinate part in comparison to clinical ideas taught by experience. Many physiological conditions intervene in connection with the vitality and functions of the bone or bones affected. Certain methods in the hands of one man yield certain results, but other men may obtain better results with other methods. In all cases a radiograph should be taken for the surgeon's own protection. Many cases properly treated at the time of injury do badly in the end from the injudicious use of mechanotherapy. The author also calls attention to the fact that the further in advance and the more the public are invited to attend courses of nursing, courses of so-called popular science, and the more pictures or anatomical specimens are shown to them, the more firmly will they hold that they are good judges in the discussion of the most complex medical and surgical questions.

Berliner klinische Wochenschrift, March 16 and 23, 1908.

The Postoperative Treatment of Carcinoma with Homogeneous Rays.—Dessauer and Krüger say that heretofore the use of radium, or Roentgen rays, has been unsuccessful in the treatment of cancer of the deeper parts, because the surface of the body is too seriously damaged before the underlying tissues are affected. Dessauer, who is an electrical engineer, after a long period of investigation, believes that he has found a method of obtaining rays which possess a deep as well as superficial action. These so-called homogeneous rays are produced by having the tubes as far as possible from the subject, by using several tubes, by screening off the ordinarily used, soft, chemical rays, and using the hard, deeply penetrating rays. Certain details in regard to the current employed are indicated, but not explained in detail. One case is reported in which the new method is supposed to have shown its special qualities. The patient was a woman suffering from a recurrence of a uterine carcinoma extirpated in November, 1905. In October, 1907, the radiation was begun, and in December the patient died, after having received 364 hours of treatment. At the autopsy, a considerable amount of carcinomatous material was found in the pelvis, but in the center of the separate nodules there were areas of degeneration which were more extensive than is usually the case. This observation the authors regard as indicating the deep effect of the rays. Burns of the surface, they claim, are not to be feared by this method, though it is possible that the liberation of toxins through cell destruction may be injurious. The method is intended only as a supplementary proceeding after radical surgery.

Gastric Disturbances in Masturbators.—Hirsch says that the great prevalence of so-called nervous dyspepsia has led to the description of a large variety of types of this form of gastric disturbance. In many cases it is difficult to distinguish between organic and functional affections and he refers to several instances in which he was led to suspect the existence of a gastric ulcer, but subsequently discovered that the symptoms were of functional nature and associated with masturbation. The patients of this category are commonly young high school and university students, who frequently come under observation laboring under the self-diagnosis of spinal disease. There is often hyperacidity, though there may be sub- or anacidity. The patients complain of severe epigastric pain, which is sometimes relieved by food, particularly milk, and by alkalies. Pressure over the epigastrium is also of service in lessening the discomfort. While it is better as a rule in the presence of symptoms pointing to ulcer to assume that this lesion exists and treat the patient accordingly, if the usual ulcer treatment fails to give good results the possibility of such a nervous condition must be kept in mind.

Münchener medizinische Wochenschrift, March 28, 1908.

Unilateral Elevations of Temperature in Appendicitis.—Widmer says that in a number of cases of appendicitis he has noticed that there was a perceptible difference in the axillary temperatures of the two sides and suggests that this fact may have interest from the diagnostic standpoint. In a recent instance in which this symptom was particularly pronounced the difference between the records obtained on the two sides at the same time varied from .3° to 1.5° C., usually exceeding .5° C. This difference persisted during the febrile portion of the patient's illness, which lasted eight days, and as the temperatures approached the normal the discrepancy between the readings on the two sides grew less until finally there was no variation. That this observation did not depend merely on some anatomical or other accidental factor was shown by the fact that a little later the patient developed a severe thrombophlebitis of the right lower extremity which was accompanied by a fever going as high at 39.8° C., but here the axillary temperatures were always alike. In explaining this condition the author speaks of the occurrence of various complications of appendicitis which appear on the right side, such as cholecystitis, subphrenic abscess, pleurisy, etc., and suggests that in analogy to the conditions of heat and swelling in the immediate neighborhood of the ordinary inflammatory affections such as localized infections, there is in appendicitis an elevation of temperature which is more pronounced on the side of the disease.

A Theory as to the Nature of Immunity in Living Tissues.—Holzinger placed sugar solutions and yeast in a clay cylinder provided with a semipermeable osmotic membrane of copper ferrocyanide. This was permeable for water but not for the sugar. The cylinder was put into a vessel of water and it was found that as compared with controls the fermentation of the sugar solution proceeded very much less rapidly under these conditions. As the result of observations conducted in this way he reaches the conclusion that a moderate degree of osmosis suffices to restrict the activity of microorganisms in fluids in which ordinarily they would flourish vigorously, while if the osmotic currents are more intense the growth of the organisms and the resulting decomposition of the medium may be completely arrested. Inasmuch as in the living tissues osmosis is constantly going on under ordinary circumstances, he considers that living tissues are immune because of this activity, and that infection becomes possible only when the tissue fluids are at rest as a consequence of such conditions as traumatic injury, blocking of the lymphatic current, drying or chilling of the tissues, etc., which bring about interference with the normal processes of osmosis.

The Tobacco Question.—Dr. George L. Meylan, physical director of Columbia University, as the result of his examinations of a large number of students, has found that most of the statements found in popular textbooks in regard to the injuriousness of tobacco are unfounded and that the average healthy young man may smoke in moderation without appreciable injury. Out of 687 students 205 were smokers. The average height of the smokers was found to be 5 feet 7½ inches, against 5 feet 7 for the non-smokers. The average weight of the smokers was 134.8, and that of the non-smokers 131.4 pounds. The strength of smokers was also a little more than that of the non-smokers.

Book Reviews.

Kokkogene Hautleiden (Furunkel, Erysipel, etc.) Von D. S. Jessner. Königsberg i. Pr. Würzburg: A. Stuber, 1907.

This pamphlet of 102 pages is devoted to the dermatoses due to the invasion of cocci, *i.e.* to impetigo, folliculitis, sycosis, furuncles, erysipelas, etc. The book constitutes a part of Dr. Jessner's lectures on dermatology for practitioners and is a very concise exposition of an important set of skin affections. A number of useful prescriptions appear in the text.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory, Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson College Hospital. March 1, 1908. Philadelphia and New York: Lea & Febiger, 1908.

The March number of *Progressive Medicine* is conducted on the same lines as heretofore, and is as readable and useful as ever. The only change is in the Department of Otology, which is now conducted by Dr. A. B. Duel of New York in place of Dr. B. A. Randall, of Philadelphia. The present issue contains the following contributions: Surgery of the Head, Neck and Thorax, by C. H. Frazier; Infectious Diseases, Including Acute Rheumatism and Croupous Pneumonia, by R. B. Preble; Diseases of Children, by F. M. Crandall; Rhinology and Laryngology, by D. B. Kyle; and Otology, by A. B. Duel.

Essentials of Modern Electro-Therapeutics. An Elementary Textbook on the Scientific Therapeutic Use of Electricity and Radiant Energy. By Frederick Finch Strong, M.D., Instructor in Electro-Therapeutics at Tufts College Medical School, Boston. New York: Rebman Company, 1907.

The author of this book is of the opinion that the absence of a simple, "up-to-date," and reliable elementary textbook is the greatest and, in some cases, the only reason for the exclusion of electro-therapeutics from the curricula of medical schools. The present work is an attempt to supply this want. That it is "simple" and "elementary" will not be disputed by any one; indeed, it is so "simple" and "elementary" that the subject of physiology from an electrical standpoint is discussed or dismissed in six pages. A large part of the book is taken up with illustrations, there being one to nearly every page of text.

Clinical Treatises on the Symptomatology and Diagnosis of Disorders of Respiration and Circulation. By Prof. Edmund von Neusser, M.D., Professor of the Second Medical Clinic, Vienna; Associate Editor of Nothnagel's Practice of Medicine. Authorized English translation. By Andrew MacFarlane M.D., Professor of Medical Jurisprudence and Physical Diagnosis, Albany Medical College; Attending Physician to St. Peter's and Child's Hospital and Albany Hospital for Incurables. Part I. Dyspnea and Cyanosis. New York: E. B. Treat & Co., 1907.

Diagnosis at long range, through the mediation of the typewritten reports of the laboratory worker has apparently become so simple nowadays that it is refreshing to turn back for a moment to the older methods of careful and thoughtful clinical observation. In this volume Von Neusser takes the two symptoms of dyspnea and cyanosis, so commonly encountered, but so often misinterpreted, and illuminates them with the painstaking thoroughness characteristic of the Vienna school. The first part of the book is devoted to these conditions, as appearing in disorders of respiration, and the second part to their occurrence in disturbances of circulation. Each of these groups is subdivided into sections in the various affections coming in question, the whole forming a model of complete yet concise description and deductive logic. The translator has done his part in rendering the text into acceptable English, and it is a pleasure to commend this admirable clinical study to the attention of all physicians.

Comparative Electro-Physiology, a Physico-Physiological Study. By Jagadis Chunder Bose, M.A., D.Sc., Professor Presidency College, Calcutta. With illustrations. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1907.

The present work by Professor Bose corroborates, by means of electrical response, the various results previously established by him in experiments recorded in his books, entitled "Response in the Living and Non-Living" and "Plant Response as a Means of Physiological Investigations." In the first book certain similarities of response in inorganic and living substances were demonstrated by means of the method of conductivity variation. In the second it was shown that plant tissues give a true excitatory response to electric stimulation. This response is not confined to sensitive plants like mimosa, but is universally present and obtainable from both the roots and stems and from the leaves of plants. Both electric twitches and tetanus were obtained in these experiments, and it was further noted that the effects on plants of fatigue, temperature, stimulants, and poisons could be definitely recorded. Professor Bose also showed very clearly experimentally, how plant energy is supplied by the environment.

The present volume is devoted chiefly to exhaustive experimentation into the electro-physiology of plants, and, to a less extent, into that of animals. For the study of the variation of excitatory effects in nerves the author has devised a very delicate instrument, the conductivity balance, the principle of which is carefully explained. Nerve conductivity and response to excitation, he finds, are similar to those of muscle. The response of the isolated vegetal nerve is indistinguishable from that of animal nerve.

The author has been able, he states, to trace out the gradual differentiation of various responsive peculiarities, characteristic of given tissues, from the simplest types in the plant, to their most complex in the animal. The attempt to explain these responsive phenomena is, in general, on the consideration of that fundamental molecular reaction which occurs even in inorganic matter.

Essentials of Obstetrics. By Chas. Jewett, A.M., M.D., Sc.D., Professor of Obstetrics and Gynecology in the Long Island College Hospital and Obstetrician and Gynecologist to the Hospital, etc. Assisted by Harold F. Jewett, M.D. Third Edition, Revised and Enlarged. New York and Philadelphia: Lea Brothers & Co., 1907.

The present represents a complete revision of the book in which it was originally intended to place the essentials of obstetrics within easy grasp of the medical student as an introduction to the more elaborate treatises and as a guide in following the didactic and practical teaching at the Long Island College Hospital and Medical School. Most attention has been given to practical topics rather than to theoretical discussions, matters of historical interest, etc. There are only eight chapters in the work, including one each on anatomy of the female genital organs, physiology of pregnancy, of labor, and of the puerperal state, the pathology of pregnancy, of labor, and of the puerperal state, and a concluding one on obstetric surgery. The illustrations are well selected and the book deserves commendation as an excellent manual for the student of obstetrics, as it is concise and yet sufficiently complete to contain all that is needed for a working knowledge of the subject. In describing the obstetric forceps the author unfortunately omits all mention of the solid blade instrument, which offers many advantages, particularly in the hands of the beginner.

Principles and Application of Local Treatment in Local Diseases of the Skin. By L. Duncan Bulkley, A.M., M.D., Physician to the New York Skin and Cancer Hospital, Consulting Physician to the New York Hospital, Consulting Dermatologist to the Randall's Island Hospital, to the Manhattan Eye and Ear Hospital, and to the Hospital for the Ruptured and Crippled, etc. New York: Rebman Company, 1907.

The author presents in four well-arranged lectures the various principles underlying the local treatment of skin diseases. Those drugs are particularly commended which have been found of value in the daily treatment of large dispensary classes. In the first lecture are discussed the relative values of exclusively local treatment and that combined with dietetic, hygienic, and other measures. The anatomy and physiology of the skin are also touched upon in relation to the purposes, effects to be expected, and necessary limitations of local treatment. In the second lecture reference is made to the ingredients, actions, and modes of applications of the various medicaments. In the third the author mentions briefly the surgical treatment connected with dermatological practice and the uses of electricity, the *x*-rays, radium, Finsen light, etc. The latter half of the book is given up to the local treatment of the more common skin diseases, special attention being accorded to eczema. The little book contains many practical suggestions not ordinarily to be found in textbooks. It is not intended for the specialist so much as for the general practitioner, and its value is largely due to the fact that, instead of mentioning a long list of prescriptions available in each disease, only a few medicaments are given, but these are known to be of proved efficiency.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

215th Regular Meeting, Held March 6, 1908.

DR. EDWARD G. JANEWAY, PRESIDENT *pro tem.*

A Bullet in the Lung.—Dr. W. GILMAN THOMPSON presented this case, together with radiographic pictures showing the bullet imbedded in the lung. The patient was a butler, who, while skylarking in November, 1907, was accidentally shot. The bullet struck the right collar bone anteriorly; here a fragment broke off, while the major part of it passed into the right lung, where it was now lodged behind the third rib, and two and a half inches from the back. For three weeks after the accident the patient suffered from profuse hemoptyses; these then ceased entirely and he was now apparently enjoying perfect health. There was no emphysema, and the bullet gave rise to no physical signs at present.

Amputation at Hip Joint for Tuberculosis.—Dr. CHARLES MCBURNEY showed this case. The patient was a boy of twenty who was operated on by Dr. McBurney nine years ago for tuberculosis involving the left hip joint and acetabulum. Prior to that he had been under treatment for about eight years, with various kinds of mechanical apparatus. He had become much emaciated, the affected limb was wasted, and there was a large sinus, communicating with the hip joint, and discharging tuberculous material. The advanced condition of disease entirely negatived any but a radical procedure. The limb was amputated at the hip, the acetabulum freely exposed, and all diseased tissue completely removed with the curette. During the operation, hemorrhage was effectually controlled, a small incision in the abdominal wall having been made, through which the finger of an assistant directly compressed the common iliac artery. The boy made an excellent recovery from the operation, his general condition rapidly improved, and he had remained well since. He now wore an artificial limb which was fairly satisfactory. In connection with this case Dr. McBurney emphasized the fact that a radical operation should not be too long delayed in dealing with some cases of chronic tuberculosis of the hip joint, which had been unsuccessfully treated for a long time by conservative methods. In some cases long-continued confinement in bed was undesirable, and in such radical measures might become imperative. The speaker said he had operated on several of these cases in a similar manner, and the shock accompanying the hip joint amputation was really slight. This he attributed to the small amount of blood that was lost in the course of the operation. Hemorrhage, as is well known, is the true explanation in many cases of the post-operative condition called shock.

Dr. GEORGE L. PEABODY said he had at present under observation a woman whose condition illustrated what would perhaps have happened to this boy if he had not been operated on. The patient he had in mind had been treated "conservatively" for tuberculous disease of the hip joint for years and she now showed amyloid changes in the liver, kidneys, and spleen. If the affected limb had been removed in time, her life might have been prolongd. She was now developing a tuberculous peritonitis.

Dr. ANDREW J. MCCOSH said that, in his experience the result in the case shown by Dr. McBurney was unusually gratifying. In fact, it was the only case he had seen in which a permanent recovery had taken place. He had been rather disappointed in the results of these operations. He entirely agreed with Dr. McBurney that in certain cases the operation was distinctly indicated. He had never before seen a patient after amputation at the hip joint who could walk as well with an artificial limb or who could bear its weight for the whole day without marked discomfort.

Dr. MCBURNEY, in closing, said that he had resorted to amputation in three cases of incurable tuberculosis of the hip, and that permanent recovery had followed amputation in all of them. He looked upon the operation in some cases as entirely rational, and he felt confident that the patient presented would have died within a year if he had not been radically operated on. He would not, however, recommend this radical procedure in cases where there was likelihood of a cure by other means. The result of such an operation was beneficial not only from a physical but from a mental standpoint. Some patients who have been subjected year after year to the confinement of an apparatus or to hospital treatment deteriorate not only physically but mentally.

Recurrent Jaundice: Death in Third Attack; with Autopsy.—By Dr. George L. Peabody. (See page 638.)

Dr. LEWIS A. CONNER said that some German writers had called attention to the fact that sugar was apt to be present during the earlier stages of cancer of the pancreas, but that it usually disappeared in the later stages.

Dr. PEABODY said that when he first saw this patient, which was only eleven days before she died, there was no sugar present in the urine, and none was found subsequently, although the urine was frequently examined.

A Remarkable Abdominal Aneurysm, with Specimen and Photographs.—By Dr. W. GILMAN THOMPSON. (See page 636.)

Constructive Surgery After Extensive Gunshot Wound of the Abdomen.—Dr. W. M. POLK read this paper and presented the patient. (See page 633.)

THE following clinical reports were presented at the 213th regular meeting, held January 3:

A Clinical Contribution on Acute Hemorrhagic Pancreatitis.—Dr. FRANCIS P. KINNICUTT, in a paper on this subject, reviewed the experimental work and clinical observations bearing upon the pathogenesis of the disease, and referred to the value of studies of the urine based upon the observations of Opie, Mayo Robson, and Cammidge, as an assistance in diagnosis. The clinical history of and anatomical findings in a case that recently had come under his observation were given in which the diagnosis of acute hemorrhagic pancreatitis had been made and confirmed at autopsy. Death occurred five days after the beginning of the illness from an intense toxemia, the result probably of autolytic products liberated in the gland. The macroscopic anatomical findings were a large hemorrhage occupying the entire middle third of the pancreas, with hemorrhagic infiltration of the remainder of the organ, necrosis, and a more or less uniform hemorrhagic exudate covering its surface. The fat necrosis was very extensive throughout the gland, in the mesentery, and in the fat tissue overlying the kidneys. There was absence of a peritoneal exudate and of a general peritonitis. A very thorough examination threw no light on the pathogenesis of the disease in the case described. The gall-bladder contained no gallstones; the common bile duct and the duct of Wirsung opened by separate orifices into the duodenum; they were free from calculi and patent throughout. The orifices of the ducts were not dilated; the accessory pancreatic duct was present, with the orifice at its usual duodenal site. The hemorrhagic exudate was apparently sterile. The gland showed no signs of softening, precluding the supposition of a bacterial invasion from the duodenum as the exciting cause of the disease. Dr. Kinnicutt said that in the light of the experimental work of Eppinger, Polya, Williams, and Busch, another possible source of acute pancreatitis in the human subject was suggested. Williams and Busch succeded in producing the characteristic lesions by forcing the duodenal contents into the diverticulum of Vater through the artificially dilated orifice. They suggested that the passage of gallstones might open the way for the entrance of these contents in

human cases. The theory necessitated the conception of the segmental contractions of the intestine described by Cannon. In conclusion the speaker suggested that the progressive familiarity with the symptomatology of acute pancreatitis should permit of correctness in diagnosis as frequently as in acute bowel obstruction and perforation of the stomach, with which the condition was most frequently confused. (This paper will be published in full later in the MEDICAL RECORD.)

A Case of Typhoid Spine.—Dr. LEWIS A. CONNER reported the case of a coachman, 42 years old, who was admitted to the New York Hospital on August 21, 1907. He was a man of good habits, and his previous history was unimportant. There was no history of tuberculosis, syphilis, or rheumatism. Four days prior to admission, after vague symptoms of two or three weeks' duration, he had gone to bed suffering from fever and prostration. His case proved to be one of typhoid fever, of moderate severity, with an unmistakable Widal reaction and a positive blood culture. On the twenty-third day of his disease, when the temperature had fallen to below 101°, and defervescence was apparently progressing normally, the patient developed severe shooting pains in the lumbar region, especially on motion. These persisted in a severe form for perhaps two weeks, and then gradually subsided; at no time, however, were they severe so long as he remained absolutely quiet, but the least change in position would give rise to excruciating pain which radiated around the back and abdomen. Coincident with this pain his temperature rose to 103.5° and remained high for three or four days; then it gradually fell, but continued above the normal for several weeks. A blood count, made on September 9 (the date of appearance of lumbar pain), showed 11,800 leucocytes; two days later the number had increased to 14,400, with 83 per cent. of polynuclears, three days later, 17,600, with 84 per cent. polynuclears. On September 12 pain in the spine was present only on motion, and jarring the spine elicited a sharp pain. There was no tenderness on pressure; no deformity nor prominence; no subcutaneous edema. Upon rectal examination, there was no tenderness over the sacrum. The reflexes were normal; there was no clonus; no Babinski. An *x*-ray picture, taken on October 7, showed a shadow completely filling the intervertebral space betwen the fourth and fifth lumbar vertebræ. On October 1 the pain had disappeared excepting on motion, and the patient was able to sit up. A month later he began to walk although his back was very stiff. This stiffness had persisted up to the present time, and prevented him from bending forwards, although his symptoms were gradually improving. The case was apparently one of typhoid spondylitis, with distinct bony changes in the lumbar vertebræ, as evidenced by the *x*-rays.

Two Cases of Injury to the Eye by Pieces of Steel, with Location of the Foreign Bodies by the Skiagraphic Method.—Dr. CHARLES STEDMAN BULL reported these cases. The first case was that of a man, 32 years old, who was brought to the New York Eye and Ear Infirmary on November 18, 1907, with the following history: Nine weeks prior to that date the right eye had been penetrated by a piece of steel flying from a lathe, and the sight was destroyed at once. Three attempts had been made in a hospital in Philadelphia to remove the piece of steel, but without success. When Dr. Bull saw him, the eyelids were much swollen, there was marked orbital cellulitis, and the eye protruded half an inch beyond the orbital margin and was immovable. The wound of entrance was on the temporal side, about 3 mm. from the margin of the cornea. There was no reflex from the fundus and the pupil was dilated *ad maximum*. A skiagraph was made of the eye and orbit, and the piece of steel was found to have penetrated the sclera posteriorly on the temporal side of the optic nerve, with its point imbedded in the lesser wing of the sphenoid. All attempts to remove the foreign body by the giant magnet failed. The patient was then etherized and the eyeball was enucleated in the usual manner, and the optic nerve divided far back towards the apex of the orbit. It was found impossible to remove the piece of steel with the eyeball, owing to its being imbedded in the bone, and it required considerable traction force by a pair of large forceps, worked from side to side, before the end could be disengaged from the bone. When removed, it was found to measure 1.75 mm. broad by 21 mm. long, and weighed 135.85 mg. The patient was now doing well, and had an excellent artificial eye.

The second case was that of a man 21 years old who was brought to the New York Eye and Ear Infirmary on December 8, 1907, with the following history: While hitting the end of a cold chisel with an iron hammer, a small piece of steel struck the right eye, causing severe pain and some loss of vision. When Dr. Bull saw the patient, six hours after the injury, there was a small wound in the sclera on the nasal side, about 3 to 4 mm. back of the corneal margin, just above the horizontal meridian, through which vitreous and blood protruded. There was no blood in the anterior chamber nor in the vitreous humor. The vision was 20/40. After dilatation of the pupil, the opthalmoscope showed a glistening white spot in the ciliary region corresponding to the external wound, and surrounded by pigment. A skiagraph was made of the eye and the foreign body was then located by the *x*-ray apparatus and its position plotted on the chart made for the purpose. Two different plates were made, and the piece of steel was found outside of the eye in the orbit on the nasal side, near the orbital plate of the ethmoid. Its apparent size on the chart was 1.5 mm. by 0.5 m. Its location was 15.25 mm. back of the center of the cornea, 2 mm. above the horizontal plane, and 12.5 mm. to the nasal side of the vertical plane. The foreign body must have struck the eye with sufficient force to penetrate the sclera, and then bounded back into its final position in the orbit. The eye was perfectly quiet and painless, and the wound in the sclera had healed, but the vision had fallen to 20/200.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 23, 1908.

DR. W. S. STONE IN THE CHAIR.

Fibroid Tumor of the Vagina.—Dr. A. REICH presented this specimen. The patient was 23 years old, married and consulted the doctor for dyspareunia. Examination revealed a bulging of the left labium majus. The hymen was ruptured, but the introitus was obstructed by a tumor. The growth could be felt extending almost four inches and laterally from the urethra to the rectum, taking in the left side of the vagina. Above and to the left the cervix could be reached; the uterus was small and anteflexed and not connected with the growth in any way. The removal of the tumor was quite simple, it being readily rolled out of its bed with the aid of the handle of the scalpel. The fresh specimen weighed 530 grams. Its length was 13 cm. and its longest diameter was 7.5 cm. The surface was nodular. On section the tumor had a distinct capsule and proved to be a fibroid with a few muscle cells. These tumors were seen in the white, but not in the colored race.

Cervical Polyp, Showing Evidences of Possible Ulceration or Early Malignancy.—Dr. A. BROTHERS presented this specimen. The patient was 46 years old, married, seven children, the last born eleven years ago. She had one early miscarriage ten years ago. The menses were regular, but continued over a period of ten days. In the intervals she noted at times a blood-stained, yellowish discharge which was free from odor. Ten years ago she

was curetted after a miscarriage. She had not complained of any pelvic trouble. The uterus was somewhat enlarged and a polyp, the size of the tip of the thumb, was seen protruding from the cervical os. This was removed and the uterus was curetted without anesthesia. The laboratory report of the hardened specimen was to the effect, at first, that the growth was benign. A later report, after the specimen had been examined by another pathologist, was that appearances looked suspicious and that it was impossible to differentiate between an ulcerated area of simple or malignant origin. He was advised to keep the patient under close observation, which he said he would do.

Irregular Uterine Discharge and Bleeding Seven Years After the Menopause.—Dr. A. Brothers reported the history of a woman, 48 years old, married 25 years, three children, the last seventeen years ago, no miscarriages. She passed the change of life seven years ago. For several months she noticed a vaginal discharge without odor and three weeks ago a little blood. She felt that she was losing weight. The vagina was relaxed, the cervix atrophied and flush with the vaginal roof. The os had a somewhat eroded appearance, evidently the result of a discharge from the uterine interior. A diagnosis of senile endometritis was made. He advised probatory section of the cervix and curettage to be followed by atmocausis. After dilating the small cervix the sound was passed into the uterus to a depth of two and a half inches. The vaginal fornix about the cervix looked loose and injected. The curette brought away very little mucosa. A portion of the cervix was exsected from each side of the cervix, extending into its canal, and the little wounds were sutured to check oozing. Atmocausis for three minutes was done with the Dührrsen apparatus, the outer shield being passed only beyond the external os, as the canal was too narrow to permit of its deeper introduction. The laboratory report of the microscopical examination of the mucous shreds from the uterine interior and of the sections from the cervix was negative. The patient would, however, have to be watched for a long period of time.

Endothelioma Discovered in a Uterine Polyp.—Dr. A. Brothers reported the history of a patient, 48 years old, who was referred to him for the removal of a fibroid polyp which protruded from the uterine canal and which was responsible for excessive hemorrhages. She was very anemic, and he did not know whether this was due to the hemorrhages or to cachexia. The cervix was slit anteriorly and the pedicle of the tumor, which was the size of a plum, was followed well up to the fundus, where it was snipped off and the uterus was curetted. The cervical canal was then sutured. The pathologist pronounced the tumor to be a distinct endothelioma. The patient refused to allow the removal of the uterus.

Adenocarcinoma of the Uterus Determined by the Examination of a Necrotic Uterine Polyp; Abdominal Hysterectomy.—Dr. A. Brothers reported the case of a woman, 45 years old, who had been having uterine hemorrhages. A necrotic polyp about the size of a plum was felt just within the external os and was removed without anesthesia, the uterus being curetted at the same time. The pathologist reported it to be adenocarcinoma. Later he removed the uterus by the abdominal route. The broad ligaments and glands were free from invasion. The patient made a rapid recovery with a prognosis fairly favorable against the probability of recurrence.

The Management of Febrile Conditions After Abortion or Labor.—Dr. A. Brothers gave an abstract of this paper, which he read at the December meeting (see page 167).

Dr. J. Clifton Edgar said that the keynote of Dr. Brothers' paper had to do with the differences in mortality and morbidity in institutional work and in private practice. He quoted figures which were accepted the world over. Mortality in institution work did not exist practically, being about 1 in 1,100. We had no accurate statistics to offer in private practice. None were published. We did not know what the mortality in puerperal sepsis was in this city, but it certainly was high, in fact too high. Many cases of septicemia in private practice were reported as cases of pneumonia, empyema, and various other conditions which masked the real cause of death. The prevention of septicemia in private practice had to do with the painstaking and conscientious attention to details. The whole subject of labor should be looked upon as one would a surgical procedure. There was a prevailing opinion among physicians, the laity, and nurses, that childbirth was a physiological process and that in a general way it would take care of itself. It would be much better if they looked upon it as a pathological process. From a study of 635 cases of immature labor there were 242 abortions in institution work and no mortality. Of 175 cases of premature labor there was one death from placenta previa. Among their cases of premature labor they had but four deaths, and one only from sepsis, making a mortality of 0.6 per cent. in tenement practice. It was generally believed that septicemia in private practice was not common. The classification of Dr. Brothers he thought was a wise one. He thought more attention should be paid to the endometrium because in a large proportion of the cases the endometrium was the first involved. It was the endometrium which gave rise to the predominant symptoms in the majority of the cases. The question of great importance arose, How much and how little to do with regard to interference. Of the 242 abortions, 211 were curetted and actively, 3 were relieved of decidua digitally, and 28 were treated expectantly. He thought they should be less aggressive as pregnancy advanced. During the last few years the inclination was to do as little as possible in the uterus, and he condemned the use of the curette. He found much benefit was derived from the use of the ice-bag; it favored involution, shut off the vessels, and inhibited bacterial invasion. Ergot acted along the same lines. He also favored alcohol injections and used 50 per cent. or even higher percentages, only when benefit resulted. The silver salts he had used extensively. He was speaking only of endometritis cases and he was sure that it was best to let the uterus alone, after making sure by digital means that it was empty.

Dr. Hermann J. Boldt asked Dr. Brothers if the gentleman who reported such a large number of abdominal sections in diffuse puerperal peritonitis, with a recovery of 60 per cent., stated in what class of cases and in what period of peritonitis the operation was done.

Dr. A. Brothers replied that the statistics concerned cases of puerperal peritonitis at different stages.

Dr. Hermann J. Boldt said that the question of streptococcic infection seemed to be one that confronted them and, so far as his personal experience was concerned, it seemed to be a serious matter. He was satisfied that, in certain forms of puerperal sepsis there was no method of treatment that was going to avail at the present time. What might come to them in the future from the use of seras he did not know, but so far as active intervention in puerperal fever or a bacteriemia might be of aid he did not know how they were going to benefit or save patients. There was another class of patients in whom the bacterial invasion was not so intense, where the amount or number of streptococci thrown into the circulation was smaller and the infection remained localized in the uterus, and subsequently became diffused and caused peritonitis. He believed in that class of patients some might be saved if they resorted to early surgical intervention. The question arose often whether the patients would not get well without operation. On the other hand, by radical operation, in cases where the peritonitis was of the asthenic form, where the patients lived three or four weeks and subsequently died, if operated upon early enough

such patients, in many cases, might have been saved. When there was a thrombosis of the pelvic vessels there was no other form of treatment which would save the patients. When he found patients ill for a few days following the puerperium and not getting better, with no products of conception in the uterus, with symptoms of septic infection continuing, under these circumstances he did not hesitate to operate. He believed the method of treatment of diffuse peritionitis by operation, flushing out the abdominal cavity with large quantities of solutions, was not going to benefit the patient. If they were left alone, with thorough drainage from below and in the sitting position, at an angle of about forty-five degrees, as suggested by Fowler, they would do better. The traumatism produced in manipulation, destroying the epithelial covering, caused a rapid invasion of the system by the organisms. In the more chronic forms in many cases early intervention would save a certain number. If the Board of Health would adopt the rule observed abroad of compelling the general practitioner and midwife to report every case in which there was the existence of septic infection, the mortality might be lessened.

Dr. Charles Jewett said that the valuable paper of Dr. Brothers was a timely one, and the oftener such teachings were repeated the better for the general practitioner. The puerperal septic mortality in general practice remained about as it was in preaseptic days. This was due chiefly, no doubt, to the fact that many obstetricians lacked surgical training; they took few or no precautions against infectious exposures and their aseptic technique was inadequate if carried out at all. Yet infection might sometimes occur independently of the obstetrician, as by the patient's own fingers or by other exposures about the time of labor. The curette in abortion was often useful for prevention if used when the uterine cavity was aseptic. In the presence of sepsis it was responsible for a large proportion of the deaths. Of five cases of puerperal infection seen within little more than two weeks, three had been curetted. Two of the curetted patients had died and the third was in a critical condition. The non-curetted patients were recovering. For treatment in the average case he relied mainly on supporting measures, plenty of water and air. Intrauterine alcohol or formalin irrigations or packs he thought of doubtful value. If the infection was limited to the uterine cavity by small cell infiltration, these measures were not needed; if the infection had passed into the deeper structures they did not reach it. While he had formerly made use of repeated douching, for the foregoing reasons he had abandoned it. Hysterectomy he had done in a few instances with little satisfaction. Successful cases were every now and then reported, but it was very difficult to define the indications. It could be of little avail except when they could be sure that the infection was confined to the uterus, and that was usually impossible. The ligation of the ovarian veins was a rational measure in infection of the veins in the broad ligament. A number of recoveries had been reported, but the operation must be done early. Most frequently the general condition of the patient was such as to discourage a major operation. He was still using the vaccine treatment in the hope of better results than he had thus far obtained. So far it had appeared to be of value in the milder and localized infections. In a case now under the opsonin treatment the woman was losing ground and was likely to die. Owing to the time required for the preparation of the vaccine from blood cultures, Prof. Van Cott, under whose direction the vaccine measures had been carried out in his service was now using stock preparations. In supposed streptococcic cases an emulsion representing nine strains of that organism had been used, pending the identification of the infecting organisms.

Dr. H. N. Vineberg said that the practice of obstetrics among the poor people was of interest to him, and to his mind there was no improvement in mortality or morbidity there. They should adopt the methods that had been adopted in Europe; that was, to have thoroughly trained midwives and have them under proper regulations. The doctors got so small a fee for waiting eight, ten, or more hours; in the practice among the poor one was expected to wait even longer than among the better class of patients. Dr. Vineberg agreed with what Dr. Brothers had said in regard to the cases of spontaneous miscarriage or abortion unattended with fever; when he came across such cases he did not hesitate to treat them as if there was criminal intent. That was borne out by the subsequent facts. They saw a large number of cases of spontaneous miscarriages without temperature, even in the dirtiest surroundings. He believed that the great trouble in private practice was that these cases were not recognized early enough; this caused the great mortality. The patients went on for some time before the true condition was recognized. No doubt in institutions the morbidity was not nearly as high as in private practice; these cases were treated at once according to the conditions presented. In Leopold's practice in Dresden he said he was surprised at the morbidity that existed. There was a class of patients not mentioned, where the women ran temperatures of 102° and 103°, and apparently in fairly good condition and without anything found on examination of the pelvis and without the uterus being enlarged. In many of these cases there might be a slight thickening of the pelvic veins. Such cases should be left alone. Fresh air was of great value in such cases. With regard to hysterectomy there were few cases in private practice in which he felt this operation was justified.

Dr. A. Brothers closed the discussion. He believed that too much blame was placed upon midwives. He was not opposed to midwives, but in this country they had not the proper regulation of them that they had in Europe. After all it should be remembered that people who live in glass houses should not throw stones, and they as physicians should not hammer the midwife. They should first make sure that their own work was up to date. When it was necessary to perform a hysterectomy in these cases he did not know.

Dr. George L. Brodhead said that too much stress could not be laid upon the importance of asepsis in obstetrics, for it was appalling to see how much of this work in the tenements was carried out. The carelessness and neglect shown was nothing less than criminal. Among the last 3,600 cases at the Post Graduate, the service being very largely outdoor, only three deaths from sepsis had occurred, showing that obstetrics, when properly done, would give a very low death rate. When confronted with a case of septic infection one should first be sure that the uterus was empty; for exploration and the removal of secundines or blood clot the fingers were the best instruments. If the uterine cavity was too long for the examining finger, one must of necessity use the curette, but it should be remembered that the curette was a dangerous instrument and should be used with the greatest care.

Dr. James N. West said that in seventeen years' practice in diseases of women he had had a fair amount of experience in obstetrics, such as would come to any young man in practice. He had had but two cases of puerperal sepsis, and both were very bad cases. In one the symptoms came on the sixth day, in the other on the eighth. Both had been infected by dirty midwives, and they both got well. The uterus was washed and swabbed with pure carbolic acid; he also used peroxide of hydrogen as a wash, following it with a 2 per cent. solution of carbolic acid. The usual supporting measures were used as well.

Dr. J. Clifton Edgar said that he limited the use of alcohol injections to those cases of endometritis with sapremic symptoms. At the Manhattan Maternity an alco-

holic injection was used after the uterus was emptied and it was repeated once unless the symptoms were better by the first injection. It was repeated once or twice only. It depended entirely upon the effect resulting from washing out the uterus.

Uterine Cysts.—Dr. Ulysses Kahn read this paper. Cases of cysts of the uterus were rare and described as curious. There were only two orders of cystic formation in the uterus. One was frequent and appeared like a complication or degeneration of primitive tumors, like sarcoma or fibroma. These were the fibrocystic tumors in which the cyst appeared as a secondary element. The second order was where the cyst appeared as one isolated and which might appear a unique phenomenon without any other lesion. He divided them into five classes. (1) Mucous or follicular cysts. The mucous cysts of the fundus were rarely met with. They did not exist before menstruation, and after its suppression the glands became atrophied and might then form small cysts. The mucous cysts were small, sessile, sometimes provided with a pedicle, and on the mucous membrane. They might number ten, twenty, or even more. The diagnosis was difficult because they did not appear to bother the patient much. The prognosis was good. (2) Hydatid cysts. These were divided into primary and secondary. These cysts might be attached to any part of the uterine cavity and might be termed interstitial, subperitoneal or submucous. They might be as large as a fetal head or an orange. They were of slow growth and it was only because of the size of the growth that the surgeon was consulted. If situated at the cervix it might be incised and drained after dilatation. If seen during labor it should be incised. If it was large and subperitoneal hysterectomy might be indicated. (3) Embryonic cysts. These cysts were always near the uterine cornua and on a level with the fundus. They lay in the midst of muscular tissue, or just under the peritoneum. They were generally small. Their shape was irregular, round, or elongated. The walls were thin. Their contents were serous or serosanguinolent. They always existed with other lesions of the genital organs. The internal wall was covered with cylindrical epithelium. On the external wall the cyst mingled intimately with the uterine parenchyma. The real cause for these cysts was the presence in the uterine parenchyma of epithelial deposits, and, for that reason, were always dependent upon a tubular inflammation. The diagnosis was difficult. The treatment was radical. (4) Serous cysts. (5) Hematic cysts. These were rare. They were of two kinds, one existing as a complication of angioma, the other was a transformation of preexisting cysts. The cyst manifested itself by the development of a tumor which might become absorbed, or give rise to repeated intracystic hemorrhages, and ending by rupture and death. The diagnosis was impossible. These cysts might contain blood, lymph, mucous tissue, or products of sarcomatous degeneration.

Dr. James N. West said the condition was an extremely rare one, and he had never recognized a cyst of the kind referred to by the reader of the paper.

Dr. H. N. Vineberg said he recently came across a cyst of the uterus. The patient had been operated upon three times, first for appendicitis, after which a hernia developed. This hernia was operated on and this was followed by suppuration. The woman left the hospital with a good-sized hernia and came to him. She had this hernial protrusion. On the left side he found a cystic mass the size of a fetal head. He looked upon it as an intraligamentous cyst. He could not tell where the cyst began and the uterus ended, or *vice versa*. He cut the uterus across and shelled the mass out. It was a cyst of the uterus attached near the left horn. There was no cleavage and he did not find any ovarian tissue. He hoped to be able to report further upon it later. Dr. Vineberg reported another case to illustrate the value of sending specimens to the laboratory. A young woman who had never menstruated, 25 years of age, had a cervix which had the appearances of malignancy. Under an anesthetic an examination of it did not impress him as to its malignancy about the marked erosion, but as an endocervicitis. He incised it and found it to be tuberculous. In dilating the cervix he found a large quantity of sebaceous material from a small cyst situated in the interior, about on a level with the internal os. It was the size of a walnut. He enucleated it, but unfortunately had not as yet sent it to the pathologist. Clinically it looked like a sebaceous or a dermoid cyst.

Philadelphia Pediatric Society.

At a stated meeting held March 10, Drs. C. F. Judson and W. N. Bradley exhibited "A Case of Sporadic Cretinism." The patient was a diminutive child, 33 months old, tardy in development, backward in intelligence, with belated dentition, coarse hair and skin, fatty masses above one clavicle and undemonstrable thyroid gland. Notable improvement followed upon administration of small doses of thyroid gland. Dr. James K. Young exhibited "A Case of Tuberculous Dactylitis." The patient was an undersized Italian boy, seven years old, who presented tuberculous spondylitis with psoas abscesses and spindle-shaped swellings of several fingers. Dr. Young also presented a report of "A Case of Streptococcic Spondylitis." The [illegible]ent was a girl who presented swelling about one ankle and an abscess at the opposite elbow-joint, in addition to inflammatory enlargement of the thumb of the left hand. From all of the lesions fluid was evacuated in which only streptococci were found. This was believed to be the first case of the kind placed on record. Drs. C. F. Judson and H. L. Carncross reported "A Case of Polyencephalitis Superior," and they exhibited the patient, a young girl, with almost perfect recovery. Dr. E. Burvill-Holmes read a paper entitled "Lumbar Puncture." He pointed out the ease and the simplicity with which lumbar puncture can be performed, and the valuable service it is capable of rendering both in diagnosis and in treatment. Dr. C. H. Muschlitz read a paper entitled "Congenital Unilateral Hypertrophy, with Report of a Case." The patient was a child four months old that presented enlargement of the upper and lower extremities on the left side, and which on *x*-ray examination was found to be due largely if not wholly to increase in the subcutaneous and muscular structures, the bones being little if at all involved. Drs. B. F. Royer and J. D. Wilson reported "A Case of Incomplete Heterotaxy with Unusual Malformation of the Heart." The patient was a child admitted to the Municipal Hospital for scarlet fever, but presenting in addition cyanosis of the surface, clubbing of the fingerends, increased area of dullness in the left hypochondrium, diminished area of dullness in the right hypochondrium, and a loud cardiac murmur. During convalescence varicella occurred as a complication and death took place on the twenty-fourth day. Post-mortem examination disclosed complete transposition of the abdominal viscera, namely liver, spleen, stomach, intestines, pancreas, kidneys, blood-vessels, and also transposition of the lungs, the thoracic vessels and the esophagus. There were five spleens. The heart, however, presented most extraordinary conditions. It was made up largely of one capacious ventricle from which both aorta and pulmonary artery took origin. In addition there was a small ventricle into which the veins entered and which communicated by means of a deficiency in the septum with the larger ventricle. The oval foramen was patulous and there was a defect in the auricular septum. The ductus arteriosus was wanting. The aorta passed backward and to the right and downward, without forming the normal arch. There was no innominate artery, the carotids and subclavians arising as independent branches.

New Instruments.

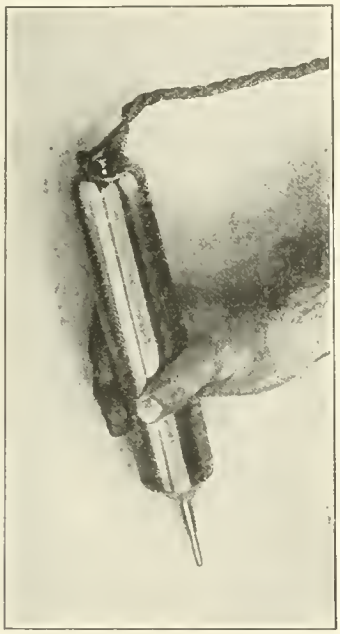
A NEW MOTOR FOR BONE SURGERY.

By W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

THE motor is of 3-10 horse power; 3 phase; 10 volts; 15,000 revolutions per minute; 185 cycles; 2 poles. Its weight is 7 pounds 5 ounces; diameter, 2⅛ inches; length of barrel, 9½ inches. The motor can be used as a drill, as a bur to enlarge a bone cavity, as a fraise to cut an osteoplastic flap, and, lastly, as a trephine.

The above description shows that this motor is in many respects a great advance on any other motor now in use. The aim in constructing it has been to make a powerful instrument, and one which is at the same time small enough to be easily manipulated. By the use of well-known electrical principles a 3-10 horse-power motor has been built, with a weight of only seven pounds, while the ordinary



Motor held in the hand, ready for use.

motor of equal power weighs about eight times as much.

The great energy and speed, 15,000 revolutions per minute, are requisite for an effective instrument, since the saving of time is often a factor of great importance. The extreme velocity is again of advantage, not only because it saves time, but also because, in an instrument which works with such rapidity, we can use a fraise with only one cutting edge. This tool has no chance to clog. The fraise does not heat, as all the heat generated is taken up by the chips. Heretofore, in other motors, the necessity of shafting or gearing has been a great drawback. Because of its small size and weight, this motor can readily be held in the hand, and thus solves the problem by doing away with either shafting or gearing. An important surgical point is that this instrument, together with its wire connections, can be sterilized.

The illustration shows the motor as held in the hand ready for use. The motor was designed and constructed for me by the International Instrument Company of Cambridge.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 11, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	570	211
Diphtheria	368	65
Measles	1877	48
Scarlet Fever	985	54
Smallpox	—	—
Varicella	166	—
Typhoid Fever	23	4
Whooping Cough	12	1
Cerebrospinal Meningitis	14	7
Malarial Fever	—	—
Totals	4015	390

French Families.—The number of French families, that is to say, households with or without children, is estimated at 11,315,000. Of this total 1,804,720 families have no children, 2,966,171 have one child, 2,661,978 have two children, 1,643,425 have three, 987,392 have four, 566,768 have five, 327,241 have six, 182,998 have seven, 94,729 have eight, 44,728 have nine, 20,639 have ten, 8,305 have eleven, 3,508 have twelve, 1,437 have thirteen, 554 have fourteen, 249 have fifteen, 79 have sixteen, 34 have seventeen, and finally 45 families have eighteen.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending April 10, 1908:

THE PHYSIOLOGICAL MECHANISM OF VASOCONSTRICTION AND VASO-DILATATION.*

By GEORGE B. WALLACE, M.D.,

NEW YORK.

WERE the arteries and veins of the body a system of rigid tubes the pressure and amount of the blood flowing through them would be dependent entirely upon the activity of the heart. A change in the pressure or blood flow in one part of the system would be accompanied by a corresponding change in every other part. Thus if a certain group of muscles in active contraction and relaxation were supplied with a needed increase in blood supply, every other organ would receive a similar increase, whether needed or not. Obviously this would imply an unnecessary waste of energy on the part of the heart.

That this condition does not exist, that an increase or decrease in blood supply to one organ or set of organs can be so offset by a change in the distribution to other organs that no particular variation in the work of the heart, or in the general blood pressure is entailed, is due to the fact that the vessel walls contain circular muscular fibers, exercising in themselves a certain tonus, and largely controlled in their contractions and relaxations by vasomotor nerves.

These nerves, the vasoconstrictors and vasodilators, control the caliber not only of the arteries but of the capillaries[1] and veins[2] as well. Their chief effects, however, are on the arterial walls, and particularly on the walls of the smaller arteries, the arterioles. On stimulation of the vasoconstrictor nerves the lumen of these is narrowed, a greater resistance to the flow of blood and a rise in pressure in the arteries ensues, the capillary and venous pressures fall, while the tissues supplied by the constricted arteries receive a diminished supply of blood and oxygen. On stimulation of the vasodilator nerves the opposite effects are obtained. Since the dilatation of a vessel could never be accomplished by muscular contraction, it follows that the vasodilator nerves which induce such dilatation must, like the cardiac vagus, be classed as purely inhibitory nerves, which lessen the tonus or contractibility of the circular muscle.

The anatomical arrangement of the vasomotor nerves and especially of their centers is somewhat complex.[3] The vasoconstrictor fibers have their centers chiefly in the medulla. From there they pass more or less directly down the cord and emerge with anterior roots from the lowest cervical or first dorsal to the second or third lumbar segments as preganglionic sympathetic fibers. These end in the ganglion cells of the sympathetic plexuses, from which, as post-ganglionic fibers, they are distributed throughout the body. The fibers which have this origin and distribution not only possess the power of effecting changes in the caliber of the vessels but in addition they maintain, by means of continuous stimuli passing over them, the tonus as well.

In addition to the vasoconstrictor centers in the medulla there is evidence of the existence of other centers, situated in the cord, especially in that region between the first dorsal and lower lumbar segments. These would seem to have less influence than the medullary centers in effecting changes in the caliber of the vessels but as much in maintaining their tonus.

A certain degree of tonus is afforded also by the peripheral structures. The sympathetic ganglion cells probably play some part in this, but the chief effect comes from either the vascular muscle itself or from the peculiar endings of the nerves in it. These are not endings in the sense of the endings of the motor nerves in striated muscle, that is they are not direct continuations of the nerve fibers, but appear to be more or less independent structures. Physiologically they are neither muscle nor nerve, but a connecting link between these two. For this reason they are referred to as the "neuro-muscular junctions."

That such "neuro-muscular junctions" exist seems established by experiments of Dixon.[4] If the post-ganglionic fiber of a constrictor nerve is sectioned, in the course of some days the part peripheral to the section degenerates completely and stimulation at any part of its course is without effect. If instead of inducing this degeneration, a certain drug, apocodein, is given, again stimulation of the nerve is without effect. In the case where the nerve has degenerated, adrenalin will cause the usual marked constriction of the vessel. After apocodein, however, adrenalin has no effect on its caliber, although the action of barium, which stimulates muscle directly, is unimpaired. There must exist then some structure which adrenalin stimulates and apocodein paralyzes, which reacts differently than the muscle, and is not affected by complete degeneration of the nerve.

I may insert here the results of certain experimental work which possess a very great biological interest as well as a direct bearing on vasoconstrictor action. It has been shown by Elliott[5] that adrenalin on whatever tissue it acts always produces an effect identical to that caused by stimulation of the sympathetic nerve supplying such tissue. Elliott[6] observed that in animals in which the adrenal glands were excised, symptoms appeared which were referable to a hindrance of the activities of those tissues innervated by the sympathetic nerves. These nerves lose their tone and may even fail to respond to direct electrical stimulation. A progressive fall of blood pressure and weakness of the heart beat are among the symptoms. At the last stages, although the nerves of skeletal muscle

*Paper read before the New York Academy of Medicine, March 19, 1908.

are quite efficient, the sympathetic nerves are affected to such a degree that nicotine, a drug which through stimulation of the sympathetic ganglia causes in normal animals a striking rise of blood pressure, is now unable to cause any rise at all. Quite independent of this, Dreyer[7] has shown that stimulation of the sympathetic fibers going to the adrenal gland brings about a very perceptible increase in the internal secretion of this gland, or at least in that constituent of the secretion which raises blood pressure. If these experiments are correct a very interesting relationship is brought to light. The vasoconstrictor sympathetic nerves require for their proper function the presence of an adrenal secretion. The presence and amount of this secretion is dependent in part at least on impulses coming to the gland through the sympathetic system.

There is no very definite knowledge concerning centers for the vasodilator nerves. It is generally believed that these are located chiefly in the medulla, although reflex centers seem to be present throughout the spinal cord. The dilator nerves leave the central nervous system as preganglionic fibers, in part with the cerebral nerves, in part with the posterior spinal nerves. They pass to the periphery usually in company with the constrictor fibers, although some are separate from these.

Different vascular areas contain different supplies of vasomotor nerves, and the general law has been put forth that the degree of contractility of vessel walls from impulses passing over the sympathetic is in proportion to their nerve supply.

That part which is most plentifully supplied with vasomotor nerves is the splanchnic area, comprising those vessels going to the spleen, liver and kidney, and especially to the intestinal tract. Owing to the immense area of arterioles and capillaries it contains, this region has most to do in effecting changes in the general blood pressure and blood distribution.

Whether the vessels of the brain, lungs, and heart contain vasomotor nerves is still a disputed question. It is certain, however, that such nerves if present are without much control over the vessels. This statement would seem to apply more to the constrictors than to the dilators. The existence of vasoconstrictor fibers in the cerebrum seems established experimentally, since a narrowing of the cerebral vessels, to be explained only by nerve stimulation, can be brought about.[8] In general, however, the amount of blood circulating through the brain is dependent upon the amount contained elsewhere, especially in the splanchnic area, that is, it is a result of not active but passive changes in the caliber of the cerebral vessels.[9] Thus constriction of the splanchnics with a lessened blood flow through them results in a dilatation of the cerebral vessels with a greater flow through the brain, dilatation of the splanchnics results in a lessened cerebral blood supply. Hence the distant splanchnics may in a way be considered as the vasomotor nerves of the brain, as far as the blood supply to this organ is concerned.

The recent experiments of Brodie and Dixon[10] may be taken as proof that vasoconstrictor nerves are not present in the pulmonary vessels. They have shown that adrenalin has the power of causing a constriction of all vessels known to be supplied with vasoconstrictor nerves. A constriction is entirely absent, however, in the pulmonary circulation, and in fact some dilatation may be induced by the drug. Nor does electrical stimulation of any of the nerves going to the pulmonary vessels cause a narrowing of them. These results have been questioned by Plumier,[11] who, using somewhat similar methods, comes to the belief that vasoconstrictor nerves are present in the pulmonary vessels.

Although the coronary vessels appear according to some authors to contain vasomotor nerves, Schäfer[12] states that such is not the case and that they are entirely absent here.

Thus whether the brain, lungs, and heart are supplied with vasomotor nerves must be considered an open question, but this in itself makes certain the fact that these vessels have at most a very scanty nerve supply, not at all comparable to vessels elsewhere.

The important service which the vasomotor system renders is to maintain a definite tonus of the vascular walls, thus keeping the blood pressure at an optimal level, and to so regulate the caliber of the vessels in different regions that each organ receives the amount of blood essential to the performance of its function.

A rise or fall in general blood pressure is usually the result of a constriction or dilatation of the splanchnic area. As a consequence of a rise in general pressure the vessels of the brain, and probably of the lungs and heart as well, undergo a passive dilatation with a resulting increase in blood flow through them. As a consequence of a fall in general pressure from splanchnic dilatation the reverse is true. With the exception of the splanchnic area, and even including parts of this, any organ may receive an increase in blood through a dilatation of its vessels with no particular rise in general pressure. This implies naturally a compensatory change in the opposite direction in other vascular areas. Such a regulation in blood distribution as this is seen especially in organs in active function, contracting muscle, secreting gland, etc. In fact, a local increase in blood supply by means of vasodilatation is the usual physiological accompaniment to an increase in function.

The final knowledge of the mechanism of such a regulation has not yet been afforded. May[13] has shown that a dilatation of the pancreatic vessels occurs when the organ is in a state of active function from the injection of secretin, although the secretion is not dependent entirely on the increase in the blood flowing through the gland. The vascular dilatation here has not the same cause as the increase in secretion, that is, it is not due to the chemical substance secretin, but according to May is to be ascribed to the formation of unknown metabolites, which, owing to their concentration in the gland, act on the vessels here and nowhere else. A somewhat similar relationship between limited vascular dilatation and increase in function has been shown in connection with the submaxillary gland,[14] while the renal vessels are dilated by urea, although this substance tends to raise the general pressure.

In the case of working muscle a dilatation of the vessels in the muscle occurs and CO_2 has been considered as a cause for this.[15] In the light of recent experiments this action seems doubtful. CO_2 has a very distinct effect on the vasomotor centers however. When brought to these by the blood it acts as a stimulant, and constriction of the splanchnics results. Whenever an organ is in a state of activity, CO_2 appears in the blood in increased amount, and it seems most probable that it is by its stimulant effects on the vasomotor and cardiac centers, that the dilatation of the vessels of the functioning organ is offset and the level of the blood pressure kept constant or raised.

A further regulatory mechanism is seen in the

vascular reflexes. These may be subdivided into one set, confined entirely to the vascular system, and a second set in which the impulses originate in other organs.

In the first set are to be found those reflexes which arise in the heart. By stimulation of pericardial nerves, of extracardiac fibers of the vagus, or of other superficial cardiac nerves, a rise of blood pressure may be obtained which is due not to changes in heart action, but to vascular constriction, especially of the splanchnics. Of what physiological importance such reflexes are is as yet unknown.

It is commonly stated that the chief afferent path over which cardiovascular reflexes travel is the depressor nerve. As a matter of fact, however, this nerve arises not in the heart, but in the beginning aorta.[16] Stimulation of it results in a splanchnic dilatation and corresponding fall in pressure, and such stimulation can come from an overfilled aorta. With a normal aortic pressure present, however, the depressor nerve has no marked regulatory influence. Thus on sectioning it the rise in general pressure is only slight. Again if the splanchnics are strongly constricted by stimulation of the vasomotor center, for instance by asphyxia, the section of the depressor results in no very marked further rise in pressure.[17] It seems probable that while it exercises a certain controlling power on blood pressure, this is rather slight, and especially so when the high pressure is due to an increased irritability or stimulation of the vasoconstrictor center.

The importance as a regulatory mechanism of other vascular reflexes seems less open to question. Thus Delezenne[18] has shown that under various influences which produce a definite rise of blood pressure through splanchnic constriction an active dilatation of the vessels of a limb takes place at the same time which is prevented if the ischiatic and crural nerves are severed. The dilatation then must be brought about by a vascular reflex. This has also been demonstrated by Gottlieb and Magnus[19] in their work on the digitalis group. Digitalin and strophanthin if injected into intact animals cause a constriction of the splanchnics and a dilatation of peripheral vessels such as those of the hind limb. If the splanchnics are all tied off the injection of these drugs causes not a dilatation but a constriction of the vessels of the hind leg. If an artificial circulation is established in the leg so that it is connected to the rest of the body only by means of nerves, the injection of either of the drugs again causes a constriction of the splanchnics and a dilatation of the leg vessels. Hence the dilatation must be an active one from a reflex starting in the splanchnics. The reflex dilatation in such a case takes in the vessels of the brain and skin and very probably of the lungs and heart as well.

Such a reflex as this is of great importance as a protective mechanism, since a rise in general pressure from splanchnic narrowing may be partly or wholly offset by the dilatation of vessels elsewhere; and it seems probable that the failure of many drugs to produce a rise in general blood pressure when given to normal animals or persons may be thus explained. So for example the subcutaneous injection of strychnine in dosage of 1-20 of a grain or of caffeine in dosage of 2 grains in a normal individual may be followed by little if any rise in blood pressure as measured from the brachial artery.

In the second set of vascular reflexes, originating outside the vascular system, are to be found those arising in the brain. Howell and Austin[20] have shown that direct stimulation of many motor areas in the cerebral cortex and of the dura as well may be followed by a very definite vasomotor response, which may result in either a rise or fall in general blood pressure. Emotional or psychic reflexes also are very common and it is a usual experience that the first blood pressure readings in a nervous individual are much higher than subsequent ones. Whether the psychic reflex produces a rise or fall in general pressure is dependent on its character and intensity. Undoubtedly in all cases the result is due largely to changes in the caliber of the splanchnics, although the heart itself is usually affected in a corresponding direction. In general the effects of cerebral reflexes are of but short duration.

The stimulation of many sensory nerves results in a rise of general pressure. Among those especially investigated are the ischiatic, brachial, and trigeminus. The rise here is again due to splanchnic constriction and again is generally accompanied by a dilatation of the vessels of the periphery, which is an active dilatation in that the peripheral dilators are stimulated synchronously with the splanchnic constrictors. In these cases the removal of the cerebral hemispheres is without effect in preventing the reflex.

The exact purpose of psychic or sensory reflexes is not clear, especially when the wide extent of the response is considered. It seems probable, however, that the mechanism has for its object the sending of more blood to the part in which the reflex starts and that the splanchnic constriction is an aid to this in that it induces a greater general pressure and so still further increases the blood flow through the dilated vessels.

A more easily explained reflex is that which follows the application of heat or cold to the skin.[21] Cold has the effect of causing a constriction of all the skin vessels although the cold itself may be applied to a limited area of the skin. Heat causes the reverse effect. Thus if a rabbit, with the exception of its head, is placed in cold water, the vessels of the ear constrict powerfully. If warm water is substituted the ear vessels dilate. Subjecting only part of the animal, the extremities, for instance, to these changes in temperature induces similar effect in distant skin vessels. The distant effects do not occur if the upper part of the spinal cord is cut, so the phenomenon is of a reflex nature.

Such a reflex as this undoubtedly has for its object the regulation of the body temperature. That the splanchnics as a rule follow inversely the changes in the skin vessels, that is, dilate when these contract from external cold, contract when these dilate from heat, is probable but not proven. It has been shown, however, that the tracheal vessels dilate quite perceptibly when the skin vessels contract from cold applications.

It is quite probable, too, that certain internal vascular regions, such as that of the kidney, may be especially affected by skin reflexes. On this subject, however, our exact knowledge is scanty.

The explanation of counterirritation assumes also a rather sharply defined vascular reflex. As Head[22] has made evident, there is a somewhat definite sensory relationship between deep lying organs and certain skin areas. Thus irritation of an internal organ is accompanied by hpyeresthesia of a fairly well localized skin area. That counterirritants applied to such an area affect the blood supply to the related internal organ by reflex action is extremely likely.

The various regulatory mechanisms thus briefly outlined are eminently physiological ones, that is,

they correlate one part of the vascular system to other parts in such a manner that the normal or physiological condition of the entire organism is maintained. In various abnormal states, however, the proper balance may be disturbed, the regulatory mechanism thrown out of gear, so to speak.

Such a disturbance is seen frequently in various nervous disorders. So for example, in nervous or neurasthenic individuals, the response to psychic or emotional reflexes may be greatly intensified. There occurs an increased irradiation of impulses from the more irritable brain cells, and so multiple impulses pass to the vasomotor centers. In this way a greater effect on these is produced and greater vascular responses elicited. That this is ultimately injurious to the organism is shown by the common occurrence of cardiac hypertrophy in some of these cases. Fainting attacks are usually to be explained by abnormal psychic impulses which cause a great splanchnic dilatation and resulting cerebral anemia. Such effects on the circulation as these differ from the normal only in their greater intensity.

In other nervous disorders the abnormal effect may be more localized. Thus a very marked spasmodic vascular constriction may be limited to one particular part of the body, a hand for example. Or from clinical histories we may assume that the circulation of some one internal organ, such as the kidney, has been profoundly altered. In such cases it would seem that the effect is not due merely to an intensification of the response to a psychic or emotional impulse but that the response has been deflected from its usual path and has been concentrated on some one vascular region. Localized vascular dilatations such as are seen in cases of angioneurotic edema may also be due to similarly abnormal reflexes.

In some other cases of regulatory disturbances the abnormality is to be looked for in the vasomotor centers. Thus in the set of symptoms classed as shock it is believed by some that the vasomotor center is in a state of marked inhibition; by others that it is in a state of exhaustion or at least great depression. The valuable work of Porter[23] tends to throw doubt on each of these hypotheses, since in shock induced experimentally he finds that stimulation of various sensory nerves results in a typical vasomotor response, in fact the percentage rise of blood pressure from such stimulation may be greater than seen in a normal animal.

By reducing the content of CO_2 in the arterial blood and so lessening the tension of this gas in the venous blood and in the tissues, Henderson[24] has produced a condition in animals which he states is apparently identical to surgical shock. There occurs a pronounced fall in blood pressure, an increase in the heart rate which may go to the point of cardiac tetanus, unconsciousness, and partial or complete loss of reflexes. In the last stages he finds in contradiction to Porter, that a reflex rise in blood pressure does not follow stimulation of a sensory nerve. When the acapnia, or CO_2 diminution, is brought about very rapidly primary cardiac failure may result; if the acapnia is more gradual, failure of vascular tonus occurs. As a result of his experimental work Henderson advances the hypothesis that acapnia is the cause of surgical shock.

In the experimental work on shock, the authors seem somewhat to lose sight of the very probable fact that just as the primary causes of the symptoms classed under this head may be most varied, so the common results of these causes may be due to quite different abnormalities of function. And it would seem unjustifiable to draw sweeping conclusions from experiments which deal only with what might be called special types of shock. However this may be, and whether one believes in the explanation of inhibition or of exhaustion of the vasomotor centers, in the interpretation Porter places on his results, or in the hypothesis of Henderson, the intimate connection between the dangerous fall in blood pressure and an abnormal state of function of the vasomotor centers stands out clearly.

These few instances of a disturbance of the regulatory vascular mechanism are cited merely as examples. It is self-evident that a better understanding of the abnormal conditions existing means a more intelligent line of treatment, and it is equally apparent that this better understanding must rest upon a sound knowledge of the physiological mechanism.

THERAPEUTICS OF VASOCONSTRICTION AND VASODILATATION.*

By EGBERT LE FEVRE, M.D.,
NEW YORK.

THE part of the subject that has been assigned to me is so wide, and can be approached from so many standpoints, that I gladly avail myself of the liberty given me by the arranger of the program to treat it from the standpoint of abnormally high blood-pressure.

From the therapeutic point of view it is necessary to have a clear conception of the condition of the entire vascular system in pathological high and low pressure. The actual degree of blood-pressure depends upon the heart, while the maintenance of that pressure depends upon the peripheral resistance. Normally the vascular system protects itself against sudden changes in pressure by the coordination that exists between different parts of the system. As the maintenance of the blood-pressure chiefly concerns us this evening, it will be necessary to consider the conditions which affect this. The following factors have been considered as having a more or less definite influence:

*Paper read before the New York Academy of Medicine, March 19, 1908.

A. The amount of blood contained within the vascular system. The regulatory vascular mechanism is such that wide variations in the amount of circulating fluid can occur without any particular change in pressure.

B. Resistance in the capillaries has been considered a factor of high or low pressure, and Broadbent and others have insisted that the viscosity of the blood has an important bearing; that any increase in viscosity means an increase in resistance to capillary flow. This, however, is not borne out by experiments. In many cases of increased viscosity the blood-pressure is indeed higher, but the explanation given of increased capillary obstruction is not the only one that can be brought forward to explain the high tension. That the blood contains certain substances that act upon the muscle tissue in the arteries and arterioles is the more reasonable. When the amount of fluid in the body is increased and is contained in the cellular and the perivascular tissues, then the edema may produce a definite obstructive effect upon the capillaries through pressure.

C. Vascular elasticity. The elasticity of the blood-vessels is a more important factor in influencing the velocity of the blood and conserving the energy of the ventricular systole than in effecting arterial tension. The changes in elasticity imply changes in the heart work and the velocity of the blood flow.

D. The tonicity of the muscle tissues in the small arteries and arterioles is the chief factor in maintaining blood-pressure. Therapeutically we should consider the muscle tissue contained in the cardiovascular system as the true parenchyma of that system, and in every case of abnormal blood-pressure with a change in arterial tonicity we should look for the cause of the change.

Conditions that cause hypertonicity in the arterial system may be due to increased irritability of the vasomotor system or of the arterial muscle, both of which conditions may be dependent upon primary toxic or primary nervous influences. The causes of increased irritability may be poisons acting upon the neuromuscular system of the circulation, which may be extrinsic, as lead, alcohol, tobacco; or endogenous, as bacterial toxins formed in the body; retained excrementory products; certain proteolytic digestive products absorbed from the alimentary canal; increased normal or abnormal secretions influencing metabolism, such as from the thyroid, or acting upon the sympathetic system, as from the adrenals; overwork, which may have a primary regional effect according to the character of the work. Probably the most important and common of these are lead, tobacco, alcohol, overeating, and a mode of life that produces the gouty condition and insufficiency of the kidney.

It is still a matter of dispute how these substances cause high tension. The older conception was that by their presence in the blood they exerted a direct action upon the muscles of the blood-vessels or on the vasomotor and sympathetic nervous system; but later, with a greater knowledge of the influence of internal secretions, both on metabolism and the cardiovascular system, there has been a tendency to put their action farther back and to consider that these substances increase the normal pressor substances in the blood, such as have their origin in the adrenal system, which system includes not only the cells of the medullary portion of the adrenals, but the chromophile cells found elsewhere in contact with the sympathetic nervous system, as Zuckerkandl's parasympathetic bodies, the intercarotid gland, Luschka's coccygeal gland, and some collections of cells in the pituitary bodies. The suprarenal glands themselves form only a part of the so-called hypertensive glandular system.

Although the manner of their action cannot be definitely explained, we know positively that these substances produce first an intermittent and later a persistent high arterial tension which causes a definite sequence of events in the entire cardiovascular system.

Regardless of cause, the changes induced by high arterial tension can be divided approximately into three stages. The first stage is characterized by persistent high tension due to hypertonicity of the muscular coats of the arteries and arterioles. This stage has been called that of presclerosis by Huchard, angiosclerosis by v. Basch, chronic arterial hypertension by Cook.

The second stage is that of progressive hypertrophy of the muscular tissue of the cardiovascular system associated with degenerative changes in the intima and fibrosis of the external coat of the arteries.

The third stage is that of diminished muscular control due to progressive fibrosis which causes increased obstruction in the arteries and arterioles of certain areas and a tendency to cardiac exhaustion and insufficiency.

The treatment must take into consideration not only the stage, but also the cause. In the first stage the increased blood-pressure due to the general hypertonicity of the arteries may at first be intermittent, but soon becomes persistent and calls for more cardiac power, which is met by cardiac hypertrophy. The increased ventricular power affects in turn the arterial system, increasing the systolic pressure, and hypertrophy of the muscle tissue in the arteries follows, so that a vicious circle is developed. From the standpoint of treatment it is necessary to recognize the fact that the hypertrophy is not limited to the heart, but extends to the entire arterial system. The so-called idiopathic cardiac hypertrophy belongs to this stage.

The first stage is the curable one and the most important part of the treatment is to find the cause and remove it if possible, or at least bring the blood-vessels under normal physiological vasomotor control. Patients at this stage frequently complain of symptoms referable to the circulatory system. These symptoms are very variable, but generally include those of cardiac overaction. On examination nothing very definite is found, except possibly a slight cardiac hypertrophy. If these patients are made to exercise while under examination it will frequently be found that the cardiac rate and force is abnormally increased, and that there is a very decided and persistent rise in blood-pressure, indicating an irritability of the vasomotor control. The development of an irritable and slightly hypertrophied heart in a young person indulging in ordinary athletic sports indicates that the arterial system is abnormally irritable with a tendency to spasm. In examining for the cause of such an irritability it is necessary to take into account all the details of daily life, food, the use of tobacco, exercise, and all those things that are likely to react on the arterial system. Increased vasomotor irritability may be hereditary. When the patient gives a family history of cardiovascular or renal disease, prophylactic measures are just as important as when there is a hereditary weakness that predisposes to tuberculosis.

Tobacco is especially apt to induce arterial spasm in susceptible persons. All those who have had experience with athletes have noticed this fact.

Tobacco interferes with their wind. If examined while under exercise they show a higher arterial tension, and suffer from attacks of dyspnea, palpitation, and precordial distress. Many persons who are accustomed to the use of tobacco find that if they change the brand to one that is stronger these symptoms are easily induced. In advanced sclerosis tobacco is sufficient to induce anginal attacks in some persons, while it causes in others acute vertigo so that the patient suddenly falls.

Alcohol also should be absolutely prohibited in all cases showing a tendency to arterial spasm.

The diet should be simple and wholesome, and while it is not necessary for the patient to become a vegetarian, vegetables should form a large portion of the diet and meat should be taken only in sufficient quantities for proper nutrition. The medical treatment of the first stage is largely directed toward increasing the activities of the emunctories. Many writers have called attention to the fact that mercury in its different forms has a marked effect on the arterial tension and that this effect is obtained quite independent of the cathartic action.

Mental and nervous excitement is an important factor in causing the arterial spasm and hastening the occurrence of the second and third stages. The physiological action of chloral on the vasomotor center and spinal reflexes explains its action in cases where emotional or mental excitement, or exaggerated reflexes, cause arterial spasm. It also has a direct action on the walls of the blood-vessels, as is shown by the dilatation of the cutaneous vessels under its use in persons with normal blood-pressure. It is rarely, at this stage, necessary to act upon the blood-vessels by the use of the more active vasodilators.

In the second stage all the factors that were present during the first stage are much more active in causing disturbances of the cardiovascular system, and there is a progressive obstruction from the arterial capillary fibrosis. As long as cardiac hypertrophy is able to compensate for the obstruction the patient may not be conscious of any change in his general health, except that on exertion cardiac action is increased and he feels the thumping of the heart against the thorax, and later there is a sense of constriction or tightness in the chest.

At this stage it is necessary to determine to what extent the obstruction to the circulation is due to the sclerotic changes in the vessels and how much is due to spasm of the muscular coats. It must be kept in mind that arterial sclerosis does not affect the entire arterial tract uniformly, but that in certain vascular areas the fibrotic changes advance more rapidly. In order to maintain a general high blood-pressure, which is necessary to carry on an efficient circulation in the fibrotic areas, the obstruction in these portions of the vascular area is met by general hypertension, which is made possible, according to Savill, only by muscular hypertrophy in the arterial coats. In the treatment of high tension this fact is lost sight of. High blood-pressure is, in many cases, a conservative process, and the indications are to control it rather than to try to reduce it to the normal level.

The danger lies on the one hand in uncompensated control, and on the other hand in overcompensated control. In the use of vasodilators it must be remembered that their effects are entirely limited to those portions of the arterial tract where the muscle tissue is still capable of exerting control, and that they have absolutely no action upon the obstruction caused by the fibrotic changes in the vessels. "Whatever true structural obstruction may be present cannot be removed; but whatever narrowing is due to hypertonus may be removed." The problem presented in each case is to what extent is it possible or safe to act upon the muscle tissue in the arteries.

When the blood-pressure is due to an overaction of the blood-vessels, before giving the general vasodilators it is necessary to determine whether or not the overaction of the muscular tissue is dependent upon some irritation that is acting upon a definite vascular area, and to remove this if possible.

High arterial tension may be due to the abnormal action of some of the normal reflexes. One of the most important of these is the gastrointestinal reflex. Some change in the arterial tension during digestion is physiological and varies with the individual, the nature of the food, condition of the digestive apparatus and vasomotor system. Normally the taking of food causes a change in the arterial distribution which is sufficient to insure the necessary blood supply to the digestive organs. Dilatation in the splanchnic area is compensated for by constriction in other vascular areas. These circulatory changes may be sufficient to cause the patient to be somewhat drowsy after a meal, or to act upon the peripheral circulation so that the patient feels chilly when exposed to lower temperatures.

Russell has called attention to a vascular reflex having its origin in the digestive organs, and has shown that this reflex is accentuated by the character of the material introduced into the digestive system, and that the continued overaction of this reflex, which acts primarily upon the splanchnic area, produces high arterial tension and hypertrophy and ultimately sclerosis of the muscle tissue in the walls of these vessels. When progressive sclerosis occurs in one vascular area there is associated with it a tendency to hypertonic contraction in the hypertrophied muscle tissue of other portions of the circulation. These facts explain the liability to the occurrence of anginal attacks after a meal, especially breakfast, as the activity of the vasomotor system is much greater in the morning than in the afternoon.

Habitual excess of proteid foods may produce hypersensitiveness of the vasomotor system. When hypersensitiveness is present slight reflexes from abdominal organs can cause sudden arterial spasm. All gastric and intestinal disturbances should be corrected. The diet should be sufficiently nutritive, but not bulky. For this reason strict vegetarian diet is contraindicated. There must be no overloading of the stomach with either solids or liquids.

The relation of the kidney to high blood-pressure is a very important one, and renal insufficiency caused by excess or error in diet is a frequent cause of presclerosis.

The fact that disease of the kidney is almost invariably associated with high arterial tension has caused kidney lesion to be considered practically the main cause of high tension and secondary arterial sclerosis. Arterial sclerosis is frequently, but not necessarily, associated with kidney disease, and chronic renal disease has been extended too far as a cause of arterial sclerosis. Its relation to arterial sclerosis may be (1) that the generalized morbid condition in the arteries, characterized by high blood-pressure, and various circulatory and nutritive effects are dependent upon other toxic conditions than those due to the kidney. The vascular change is a general one and the renal vessels take part in it. (2) Primary renal disease may induce cardiovascular changes and arterial thickening.

There is need of separating these two kidney conditions both etiologically, pathologically, and therapeutically. Why primary kidney lesions are so constantly associated with high blood-pressure and changes in the cardiovascular system has generally been explained by the retention of substances that should ordinarily be thrown off by the kidney.

Therapeutically, I have always considered that there was another explanation of it, namely, that in primary kidney disease there was interference or obstruction in the kidney circulation which demanded a higher arterial tension to afford the requisite blood supply for the proper functioning of the kidney. As the circulation of the kidney is part of the splanchnic system the high pressure, needed to maintain a sufficient kidney circulation, can only be obtained by changes in the general splanchnic circulation, and as a result the normal splanchnic control over blood-pressure is disturbed. By the use of such diuretics as theobromine, which dilates the renal vessels especially, we may bring more blood to the kidney and so remove the necessity for this general higher pressure. All are agreed that these substances lower excessive arterial tension when they increase the kidney function, but there has been no very definite explanation of how they could influence the splanchnic area.

When high blood tension is associated with kidney disease the degree of blood-pressure as such is considered too exclusively, and the fact is lost sight of that there is need of a higher blood-pressure to carry on an efficient circulation in the diseased kidney. It has been very aptly put that "it would be better for a man not to have a sclerotic kidney, but if he has a sclerotic kidney, it is well for him that he has a high blood-pressure." This high blood-pressure, while necessary for the kidney, carries with it dangers elsewhere, and the problem is to keep the pressure at a point which is sufficient for kidney circulation and safe as far as the general vascular system is concerned.

In the later stages of arterial sclerosis when edema occurs, associated as it nearly always is with some change in urinary secretion, the tendency has been to direct our efforts entirely to increasing the urinary flow, although in many cases, with the exception of a slight change in the amount of urine, the evidences of the kidney changes are rather indefinite. I desire especially to warn against the use of immense quantities of water given for its diuretic effect. The circulation in these cases is already overtaxed and there is an excess of fluid in the body. The giving of large quantities of water only adds to the blood mass and increases the work of the heart. There should be marked fluid restriction, free elimination by the bowels and skin so as to bring the fluid content of the body within the power of the heart and the vessels.

Excessive blood-pressure does not itself constitute an absolute indication for treatment and the active vasodilators should be used only to meet emergencies as stenocardia, angina pectoris, and the cerebral disturbances. The vasodilators of the nitrite group, as nitrite of amyl and nitroglycerin, ordinarily have only a temporary effect, and when sustained high pressure is associated with disturbances that cause anxiety, they should be given cautiously and the pulse watched. No sudden or extreme action from these drugs is desirable. They should only be used to meet emergencies.

The effect of the vasomotor dilators is not entirely gauged by the fall of pressure, but by the patient's subjective feelings and the pulse rate. Because these dilators in many cases do not materially lower the blood pressure, many have claimed that they are absolutely useless. In cases of extreme sclerosis, where the obstruction is due to the fibrotic changes rather than the hypertension in the muscles of the arteries, these drugs have a very limited effect upon the blood-pressure; nevertheless, many of the symptoms from which the patient complains are relieved by their use. This is due to the readjustment of the circulation, which is made possible by the drugs acting upon the vascular areas where the muscle tissue in the blood-vessels still exerts control. Vasodilators can only reduce blood-pressure permanently when the heart is failing. If under the use of these vasodilators there is a permanent fall of pressure, a quickened pulse rate and no improvement in the patient's well-being, then it is an indication that there is a weak heart and that the high tension necessary to carry on efficient circulation in the important vascular areas is lacking. This is especially true in the last stage of Bright's disease with cardiac dilatation and dropsy. The fact that the case was primarily one of high tension shows that this tension was necessary for the kidney function.

I am thoroughly convinced that the present inordinate use of vasodilators to control arterial tension is not altogether free from danger, and that there is a secondary effect from their use, which shows itself in an increased tendency for the hypertrophied muscle tissues in the vessels to be thrown into spasm under slight reflex irritation. My experience in the treatment of cardiovascular diseases dates back to a time before the vasodilators were used as freely as at present. While patients suffered from anginal attacks then as now, the attacks in the early stages of the disease were not as marked as at the present time. In a certain percentage of cases the use of nitroglycerin causes a temporary rise in arterial tension immediately upon its administration. This is followed by a very great relaxation of the vessels, but when the effect wears off the irritability of the vasomotor control is markedly increased.

Control of high blood-pressure by cardiac sedation is not justifiable except in cases where cardiac hypertrophy is excessive and cardiac overaction occurs under nervous excitement or physical exertion.

We have frequently to decide the question whether altitude is contraindicated in persons with high blood-pressure. Observation shows that the first effect of altitude is to raise arterial tension even in normal persons, but after a few days' residence the pressure falls and later may be lower than before. This has been explained by the effect of the rarified air upon respiration and surface circulation.

As persistent high blood pressure is dependent upon disturbance in the splanchnic area which exerts the normal physiological control over the circulation, one of the most important methods of treatment is the use of those means which influence vascular dilatation in the skin area, as baths, counterirritation, and high frequency currents; and in the muscles, as massage and restricted exercise. One must at the outstart determine how great the disturbance in the splanchnic area is, *i.e.* to what extent the part it plays in the normal regulatory mechanism is lost. The principle of such treatment consists in causing a dilatation of peripheral vessels, and so a compensation for lost splanchnic control. In a word, it is the educating of the peripheral vessels to control the circulation. Unless

these desired effects are obtained, such treatment may be decidedly harmful. This fact is frequently lost sight of and baths, massage, or restricted exercises are advised, without any definite knowledge of the patient's reactive powers, or observation of the patient during and after the use of these remedial measures.

In prescribing baths it must be remembered that the blood-pressure can be either raised or lowered according to the kind of baths used. In high blood-pressure the object desired is dilation of the superficial vessels and slowing of the heart, which is the reverse of that aimed at in low blood-pressure, viz., contraction of the peripheral capillaries and so-called "tonic" effect.

Cold baths of plain water raise the arterial tension. If the patient reacts quickly this rise will be of short duration. In cases with high tension, especially if there is beginning myocardial insufficiency, the reaction does not readily occur. On the other hand, in patients who have always been accustomed to take cold baths, who have educated their peripheral circulation, reaction quickly occurs. It is dangerous to begin with the baths at the temperature ordinarily advised, 90° to 92° F., in patients unaccustomed to cold baths. The temperature should be at 99° to 101° F., and at subsequent baths the temperature may be lowered, but only when the patient reacts quickly and the initial rise is followed by a decided fall in pressure.

In patients who suffer from anginal attacks when exposed to cold air it is very necessary to educate the peripheral circulation by a graded course of baths.

Water that contains saline material, as salt or calcium chloride, or sulphur water, causes a quicker reaction through its effect on the cutaneous vessels, and can be used colder than plain water. The fall of pressure is more marked and lasts longer.

If to the effect of cold pressure is added in the form of spray or strong needle douches to the entire body, the blood-pressure is raised and persists for some time (tonic effect).

Hot baths reduce the blood-pressure to an extent roughly proportionate to temperature. Hot air or Turkish baths, although raising the pulse rate, reduce the pressure still more than plain hot baths. Moist hot air or Russia baths lower the pressure. The effect of Turkish and Russian baths is modified if cold douche or needle bath is used afterward. The pressure is raised again according to the strength of the douche and the coolness of the water. The alternate hot and cold douche (Scotch douche) raises the blood pressure when the temperature varies rapidly.

The saline baths and effervescing saline baths (Nauheim baths), even when used at a lower temperature than the plain water bath, lower the pressure more and have a cumulative effect, so that after a course of baths the pressure is permanently lowered in suitable cases.

It cannot be too strongly emphasized that the bath treatment, whatever form used, must be adapted to the individual patient, all the details, as temperature, duration, amount of saline, and degree of effervescence, must be determined, and after the bath the coudition of the patient should be observed. The good effects of the treatment depend on the ability of the blood-vessels to respond and the control of the vasomotor system over the circulation. When high blood-pressure is due to general fibrosis but little can be accomplished. The same is true when there is marked myocardial weakness.

Massage can raise or lower blood-pressure according to the nature of the movements and whether the abdomen is included or not in the treatment. Effleurage (which includes all stroking movements), tapotement (which includes all percussion movements, as slapping, tapping, beating, clapping, chapping, or hacking), and vibration raise the blood-pressure, while pétrissage (which includes all pressure movements, as kneading, rolling, squeezing of the muscle tissues), after a very slight and short initial rise, reduces blood-pressure if applied only to the extremities and trunk. If the abdomen is included, then there is a rise in pressure.

If a vasotonic effect and increase in blood-pressure is desired, the lighter motions, as stroking, percussion, and vibration of the extremities, and kneading, ending with light percussion of the abdomen, is used. If the object is to reduce blood-pressure, the slow, intermittent rolling or kneading of the muscles of the extremities, back, and trunk should be employed, but the abdomen should not be manipulated at all. The treatment should be given in a warm room, so as not to cause contraction of cutaneous vessels.

Passive or resistant exercise gently performed causes a slight initial rise, followed by a fall in blood-pressure during the continuance of the exercise, and a still farther subsequent fall which persists for a varying time. The movements cause a dilation of the blood-vessels in the muscles similar to that produced by massage. If the movements are too energetic or the patient does not breathe quietly during the exercise there is a decided rise in the blood-pressure. Considerable experience is needed to give the exercises properly, and the movements must be adapted to the patient.

The power of the iodides to relieve some of the symptoms caused by high blood-pressure has long been recognized. Balfour, years ago, called attention to the alleviation of pain in aneurysm of the aorta under their use, and showed that it was not due to the effect on the supposed syphilitic change in the artery. The effect was formerly supposed to be due to a lowering of blood-pressure, but since the introduction of the sphymograph it has been shown that the relief is obtained before there is any reduction, which occurs only in certain cases and after long use. Romberg believes that iodides act by reducing the viscosity of the blood and so lessen the work done by the vascular system. While there is some reduction in the viscosity of the blood, it is not sufficient to account for the effect, and when the viscosity is reduced by other agents even more than it is by the iodide of potassium, there is no amelioration of symptoms or fall of pressure. Recent investigations into the relation of iodine to the functioning of the thyroid gland suggest that it may influence thyroid secretion and so act on the vascular system. This is in line with the action of small doses of thyroid extract on blood-pressure. While thyroid extract does have an effect on high blood-pressure, it is not a medicine that can be entrusted to the patient, as the dose must frequently be changed, and, with any symptoms of hyperthyroidism, stopped. It is much safer to use the iodide of potassium. Rarely more than fifteen grains of the iodide of potassium a day in divided doses is needed, and it should be continued in well marked cases for two or three years, with an intermission of ten days to two weeks every two or three months. Usually it is given in too large doses and for too short a time. If combined with sodium bicarbonate, gastric irritation is avoid-

ed. It should not produce symptoms of iodism. In the late stage of the cardiovascular or renal disease with edema of the lungs or general edema, it should not be used.

THE TREATMENT OF ENDOMETRITIS BY IRRIGATION AND DRAINAGE.*

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

Clinically endometritis may be classified as (1) catarrhal; (2) septic; and (3) senile. The catarrhal type has two stages: subacute and chronic. The septic variety has also two stages; acute and chronic. But senile endometritis is essentially a chronic condition and has therefore only one stage.

Gonorrheal endometritis, though belonging to the type designated "septic," should be placed in a class by itself.

Catarrhal endometritis, though denied by some authorities, undoubtedly occurs independently of any primary infection, being caused by repeated and prolonged congestion. As evidence of the truth of this statement a condition that may be designated catarrhal endometritis is found in virgins where there has been no possible chance of infection. Infection may occur subsequently, but it is secondary to the original condition. In the catarrhal type of endometritis the chronic stage develops from a long continued subacute process.

Septic endometritis is either acute or chronic. It is questionable if it develops as a chronic condition without any previous acute stage as stated by some authorities. The process of development may be gradual, especially in endometritis of gonorrheal origin spreading from a mild infection of the cervix, but there is nothing to prove the nonexistence of an acute stage at some period of its development.

Gonorrheal endometritis, or endometritis resulting from invasion of the gonococci should obviously be considered apart from other forms of septic endometritis. Its consequences are more serious and the treatment must be more vigorous and more persistent, not only to establish a cure, if that is ever possible, but also to thwart the occurrence of disastrous sequelæ, too well recognized to require more than passing mention in this connection.

Senile endometritis is essentially a chronic condition, the result of atrophic changes following the menopause. It may or may not be a distinct inflammatory process. That is unimportant. Its treatment, to be effective, involves the same principle as the other types of endometritis, viz., drainage.

The fundamental principle in the treatment of endometritis, in whatever form encountered, is or should be drainage, not of the cavity alone, but drainage of the submucous glands as well. In conjunction with drainage, cleanliness is likewise essential. This should comprise removal of accumulated secretion and débris from the cavity of the uterus, and agglutinated, viscid secretion from the surface of the mucous membrane of the cervix by copious irrigation, repeated at least daily. This is accomplished by means of a special double current or return-flow irrigator, made sufficiently small to permit introduction through the canal without previous forcible dilatation such as is required for curettage. Sufficient dilatation for introducing this small irrigator is secured, when necessary, by means of conical electrode dilators, introduced through the canal while connected with the negative pole of the galvanic current. A moderate current of 10 M. will suffice and this does not irritate or cauterize. Thus negative electrolysis is utilized to free the canal for irrigation and subsequent drainage. As a rule this irrigator may be introduced without the preliminary dilatation, or it may be converted into an electrode by insulating it with a piece of rubber tubing slipped over it, there being an attachment for connecting it with the wire from the battery. In this manner its introduction is facilitated. Throughout the irrigation the current should be continued in force in the same moderate strength.

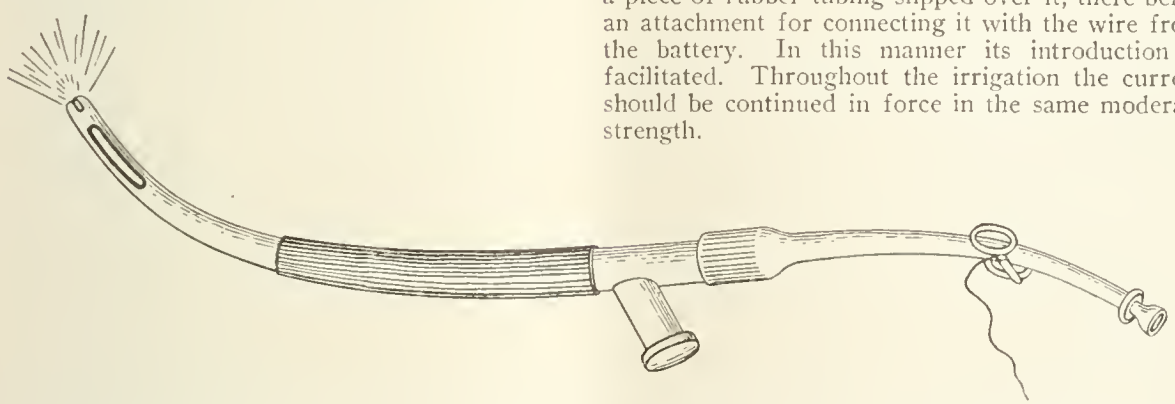

Fig. 1.—The author's clinical uterine irrigator; showing connection for current and rubber tube slipped over it for insulation.

Negative electrolysis thus employed not only establishes and maintains free drainage from the cavity by rendering the canal of the cervix patulous, but also serves to drain the submucous glands by freeing the orifices of the ducts of these glands opening upon the surface and stimulating the glands to throw off pent-up secretion. This is what I have elsewhere designated "drainage of the glands."

This is by no means a theoretical proposition, but a method of treatment for these conditions that has had many years of abundant clinical test, and in my hands it has yielded results that are most gratifying.

The solution used for irrigation will vary with the individual condition under treatment. It may be simple sterile water, normal salt solution, permanganate of potassium (1 to 3,000 or 5,000), peroxide of hydrogen (1 to 4), lysol (a dram to 2 qts.), which facilitates removal of the viscid secretion, or iodine in the strength of one dram of the tincture to three or four pints of water. When iodine solution or other astringent or antiseptic solutions are used in the uterus care must be observed to let all of the solution escape before the irrigator is withdrawn or contraction of the cervix may occur causing retention of the solution and provoking severe pain. This is the most effective method of cleansing the cavity and making applica-

*Read by invitation at session of the Tri-State Medical Association of the Carolinas and Virginia, at Charlotte, N. C., February 18 and 19, 1908.

tions thereto. The thoroughness of the application and subsequent drainage is assured.

Method of Dealing with Individual Types of Endometritis.—Subacute endometritis will subside upon removal of the cause of the general pelvic hyperemia and in conjunction therewith the use of depleting tampons in the vagina. For this purpose iodine and glycerine in the proportion of 1 to 32 or a dram of the tincture to four ounces of glycerine is to be preferred.

In the acute stage of endometritis the canal is usually patulous, the uterine wall, including the cervix, being soft and yielding. Drainage is therefore, as a rule, sufficiently provided for by nature's process and dilatation is not required. Irrigation is, however, essential, especially in the gonorrheal type. In this stage prolonged irrigation with very hot solution of a mild non-irritating character will be most effective. These irrigations should be repeated daily and absolute quiet, preferably in bed when possible, should be enjoined. When its origin is gonorrheal infection irrigation with a mild solution of permanganate of potash (1 to 5,000) or iodine (one-half dram of the tincture to 2 quarts) is permissible. Attention to the bowels which should be kept loose with salines and regulation of the diet is very essential. Pain may be allayed either with a hypodermic of ½ grain phosphate of codeine or a rectal suppository of aqueous extract of opium ½ grain.

In the chronic stage the mucous membrane is thickened from infiltration and there is more or less induration, especially in the cervix and about the internal os. Consequently the caliber of the canal is diminished and often so much occluded, that drainage from the cavity is seriously interferred with or positively prevented. In this condition, when curettage is not required, negative electrolysis to free the canal for drainage with irrigation as described above will prove effective. When displacements are encountered they should be corrected in the course of the treatment, first by means of carefully adjusted tampons and later a properly fitting pessary. The iodine and glycerine tampons will prove a valuable aid, both by reason of the depletion they induce and the support they afford the uterus.

In gonorrheal endometritis cleansing of the cavity will be more effectual if it is first washed out with a solution of peroxide of hydrogen (1 to 4) through the return flow irrigator, the solution of permanganate or iodine being used subsequently. When the infection is confined to the cervix swabbing out the canal up to the internal os with peroxide solution (1 to 2) and subsequently similar applications of nitrate of silver solution is the best method of treatment.

The indiscriminate application of strong, irritating solutions and caustics to the endometrium cannot be too strongly condemned.

Utility of the Curette in Endometritis.—Curettage is sometimes required in the treatment of endometritis for expediting its cure. It should not, however, be employed in the acute stage. Likewise it should not be employed with the mistaken idea that it will cure the condition unaided. There is no doubt that this operation has been much abused and that its mode of action has been misunderstood. Curettage is to be regarded only as an initial step in the treatment and never as a curative measure alone. Subsequent drainage and cleansing of the cavity is quite essential for a cure. The dull or semi-sharp instrument only should be used in the cavity, the sharp curette being sometimes required, however, for the tougher tissue at the internal os and in the cervical canal. The purpose of the curette is to remove areas of mucous membrane projecting above the surface that may be blocking the ducts of the glands opening upon the surface, and by the pressure exerted expressing their contents. Subsequent irrigation is necessary to maintain drainage of these glands.

I would not be misunderstood as decrying this operation. Under proper limitation when indicated it is most effective and is without equal. But I do most emphatically denounce its too frequent abuse and misapplication.

In the treatment of senile endometritis irrigation is seldom required and then only in the beginning of treatment to cleanse the cavity when there is a large amount of retained mucopurulent discharge. As a rule, if the canal of the cervix is made patulous by the application of negative electrolysis through the dilating electrodes the resulting drainage will establish a cure At the outset the very smallest dilating electrodes only can be introduced because the structure of the cervix is indurated and frequently the canal is completely occluded by cicatricial tissue that has replaced the mucous membrane in the canal. After a few applications have been made the dilatation accomplished will permit the introduction of a larger size. Never more than 10 M. of current should be used as cauterization is undesirable. The applications should be made every second day in the beginning and later less frequently but they should be continued as long as there is any evidence of discharge from the cervix.

In conclusion I desire to quote here extracts from a paper presented by me at the Section on Diseases of Women at the Fiftieth Annual Session of the American Medical Association, held at Columbus, Ohio, June 6 to 9, 1899, to show that my views upon this subject have not been materially altered by a more extended experience.

"As an actual fact endometritis is not so common as is generally supposed, hyperemia of the endometrium being often mistaken for it. . . . Another condition often mistaken for endometritis is the so-called cervical catarrh. The diseased process is, as a rule, confined to the canal of the cervix and does not extend beyond the internal os, unless the infection, usually of a passive type, is conveyed to the cavity above by the introduction of instruments for diagnosis or treatment, or for operation, such as dilatation and curettage. The condition is usually an infection of the glands of the cervical mucosa, and manifests itself by a discharge, sometimes inoffensive in amount and insignificant in appearance, yet in it may be found the staphylococci, streptococci, or gonococci, either alone or together. They appear in small numbers in the ordinary discharge, but when the surface is irritated the discharge is increased and their number is greatly multiplied. This means that these bacteria inhabit the glandular structure and few escape to the surface under ordinary conditions, the orifices of many of these glands being obstructed, but under unusual stimulation the pent-up secretion is thrown off in greater quantity and with it myriads of these bacteria which otherwise would not find their way to the surface.

"*In such a condition the cavity of the uterus should not be invaded even for the purpose of diagnosis until all evidence of germ growth, as revealed by the microscope, has been effaced.* The penalty of violation of this rule is risk of infection of the endometrium, which previously may have been exempt. Obviously the most rational manner of

dealing with such infection, which is not confined to the surface of the mucous membrane, but has invaded the granular structure beneath, is to stimulate the glands to throw off the pent-up secretion and to irrigate the surface frequently with a non-astringent, nonirritating solution to remove the secretion and prevent migration. This process of 'drainage of the glands,' if persistently maintained, will cause the bacteria to be thrown off too rapidly for effective propagation in the glands, hence their growth is checked and they become eventually exhausted.

"The same holds true of inflammation of the mucous membrane of the cavity above the internal os. The glandular structure is involved and no form of application to the surface can accomplish a cure unless its effect is to establish and promote drainage of these glands. If it defeats drainage, it must aggravate the condition. Applications that coagulate the secretion on the surface block up the orifices of the glands. Hence astringents and caustics defeat drainage and are therefore contraindicated.

"Curettage is of service both in the canal of the cervix and within the cavity of the uterus, but it should not be employed indiscriminately. To accomplish the most good it should be employed within proper limitations, and caustics should not be applied afterward, since they produce necrosis which may result in atrophy of the mucous membrane or agglutination of the sides of the cavity. . . . The object of curettage is not to destroy the mucous membrane but to remove superfluous tissue that may be blocking the orifices of the glands and preventing drainage. Probably much of the benefit that accrues from curettage comes from stimulation and compression of the glands from passage of the curette over the surface of the mucosa. This forcible expulsion of the secretion would as much as anything remove the obstruction of the gland ducts.

"Since it is not in itself curative in these conditions curettage should be regarded only as a preliminary step in the treatment. Evacuation and drainage of the glands made possible thereby must be maintained and frequent irrigation through the return flow irrigator must be employed until no vestige of the disease remains. This is the only positive way of effecting a complete cure."

2230 Broadway.

SCIATICA.*

By M. L. BARSHINGER, M.D.,

York, Pa.

It is the history of medical progress that with increasing knowledge has come a better understanding of disease. And with the better understanding of a disease better methods, as a rule, have closely followed for its control.

The condition which is described and which we know as sciatica suggests itself for profitable study along these lines, especially in view of the fact that it is recognized as being of frequent occurrence, of great severity, and showing a tendency to become chronic. Moreover, from the time it was first described the skill of the profession has been baffled to conquer it.

Sciatica is described in our text books as being, as a rule, a neuritis either of the sciatic nerve or of its cords of origin; or, in some instances, as a functional neurosis or neuralgia. This, however, does not seem to be an accurate description, as the whole truth, particularly with reference to the important factor operating in its production, does not appear, which factor if recognized on the part of the profession is not appreciated with respect to the means at our command for its control. This factor operates perhaps in at least seventy-five per cent., it may be more nearly correct to put it as high as ninety per cent., of the cases. Sciatica, therefore, as a neuritis, is to be recognized as a secondary affection largely dependent upon this operating cause.

The favorite seat of this affection is the sciatic notch. The patient will refer his pain to this point. Frequently there will be pain in the back of the thigh, at about the lower third. As the affection progresses and the structure of the nerve becomes involved pain may be almost anywhere in the leg. A brief reference to the relationship of the structures which exist at the sciatic notch will present a perfect picture for the study of what takes place in the production of this disease. It will be seen that the sciatic nerve, as it leaves the pelvis and enters the thigh, passes through the notch together with its accompanying vessels, resting anteriorly close upon the bone of the pelvis. Posteriorly, lying immediately over it and resting close upon the nerve, is seen the pyriformis muscle.

Given now the usual history of rheumatism or of gout, exposure after heavy muscular exertion, or a severe wetting, and pain referred to the sciatic notch, what is likely as having taken place? It is a reasonable presumption that the muscular structure has become the seat of a local irritation rather than any nerve structure which happens to be present, as is the nature of such irritating influences when the body is being subjected to them.

The pyriformis muscle, therefore, having become the seat of an irritation, and as contraction follows as a result of irritation to muscular structure, it must necessarily impinge upon the sciatic nerve. And if, as is also usually the case, a congestion and swelling of the muscle accompany the irritation, it will not only impinge upon the nerve, but will bear down upon it against the bone of the pelvis and hold it tightly as in the grip of a constricting band, it being impossible for the nerve to escape, the amount of pain and disability being in direct proportion to the degree of compression.

I have seen striking evidence of the action of the pyriformis muscle upon the sciatic nerve as the result of a strain following the lifting of a heavy stone; this located itself in the sciatic notch, producing the intense pain and disability of a typical sciatica. It does not necessarily follow that the pyriformis muscle is always, primarily, the seat of irritation, as it may be readily conceived that the muscular structures adjacent and intimately associated with it may be in a state of irritation and the process conveyed to it by extension.

The occasional shooting pains down the leg of which our patients sometimes complain, particularly in the male subject, are probably due to momentary spasmodic contractions of the pyriformis muscle upon the sciatic nerve.

I have been particularly impressed in the study of my cases that true sciatica in woman is probably exceptionally rare. It does not seem that women who are subject to hard work and exposure appear for this reason to be more especially prone to the disease than those more favored in life. I have no doubt that woman is more exempt from this affliction because of her anatomical structure, the bones of the pelvis being lighter and more expanded, affording more room for the escape of the sciatic

*Read at a meeting of the York County (Pa.) Medical Society, March 5, 1908.

nerve from compression so far as the pyriformis muscle is concerned.

Other observations which may be noted are that the left side is more often the seat of the affection, no doubt owing to a slight difference in the anatomical structure of the two sides; that men who do not live lives of exposure do not seem to be afforded special protection on this account; and that there seems to be an hereditary predisposition in some to begin to suffer from the disease some time during middle life.

In the study of the development of a neuritis of the sciatic nerve, while the predisposing or exciting cause is to be found, as a rule, in the action of the pyriformis muscle upon the nerve, it is to be considered only as the initial stage in an attack of sciatica, as no involvement of the structure of the nerve, as yet, has taken place. It is only after a continued and persistent pressure that the nerve itself becomes affected, with loss of function and of nutrition, which, if not arrested, will threaten the integrity of the nerve, as well as the usefulness of the leg.

The pain which so often occurs early in the back of the thigh is also an important feature in the development of a neuritis. It usually locates itself at or just above the division of the nerve into its two important branches, which generally takes place at about the lower third of the thigh. The pain at first is but an expression of an interference in the function of the nerve which is being inhibited by undue pressure at the notch, but it is also indicative of the great strain to which the nerve is being subjected at this point by reason of the great activity here of the nervous mechanism in the transmission of the nerve impulses to their proper destination.

The integrity of the nerve structure becomes threatened, therefore, at two distinct points, and as a result two lesions in the nerve may be developing almost simultaneously. In the advanced stages, especially in the most pronounced manifestation of the disease, the extent of the involvement of the nerve and its branches is, perhaps, impossible to determine.

In the diagnosis, care is of course required lest a painful sciatic nerve is but the reflection of disease of the spinal cord or of the hip joint; or of a loaded rectum, hemorrhoids, pressure due to sitting on the edge of a chair or stool, flat-foot, or the pressure of badly fitting shoes.

The constitutional conditions, as syphilis, alcoholism, diabetes mellitus, malaria, and toxic effects in general, are to be mentioned more as contributing influences in the production of an irritation of the pyriformis muscle than of the sciatic nerve.

Sciatica being the exception in woman, pain in the course of the sciatic nerve should always direct the attention first to the intrapelvic region, as the nerve within the pelvis, the sacral plexus, may be compressed by a tumor, ovarian or uterine, or a malposition of the uterus may be the source of irritation. This pressure symptom is often seen during the course of pregnancy, and to a greater degree in the process of parturition.

It is now some eight or nine years ago that Osler, with a case of sciatica before us, made the statement to this society that "the best treatment of sciatica is six months"—an apt summary, undoubtedly, of the inefficiency of the usual measures employed, as well as a significant statement of our utter helplessness in the face of a torture which this disease has imposed upon its luckless victims.

But somewhere in the great domain of the science of medicine progress is continually going on from which blessings issue unto a suffering humanity. Having arrived at our present state of knowledge in the recognition of an offending and sinister muscle menacing the welfare of the sciatic nerve, and capable of inflicting a distressing malady, the means for its control are also found to be at hand.

Now I have a proper regard for the spirit of skepticism, as well as the indifference, unreasonable though it may appear to be, which obtains on the part of many when the subject of physical therapy is presented. It is, therefore, no wish of mine to do too much violence to these feelings. At the same time it is incumbent upon me to present the facts which my experience has shown them to be. A clinical experience extending over four years in the use of physical agents has afforded me an opportunity of acquiring more or less familiarity with their value in various conditions. What may be expected of them in this affection?

In order to show what was accomplished in a subsequent attack in the patient to whom I have just referred the following history may be presented. Two years ago this patient was seized with a second attack, after being threatened for about one week, in the same way as in the development of his first attack. On the following day, with great difficulty, by the aid of two canes and the assistance of his son, he was brought to my office for treatment. The result of the treatment was that so much relief and comfort was secured that he was enabled to walk about without any assistance, either on the part of his son or from his canes, and he so left my office, and after three days he was fully restored to the normal condition, and has remained perfectly well since.

I may likewise also again refer to the case as the result of a strain. This patient, too, had great difficulty in getting to my office on account of pain and disability. Immediately after treatment he was able to return to his work, and three treatments, in as many days, were sufficient to restore him to the normal.

This has been a fairly constant and uniform experience of mine in the control of the initial stage of an attack of sciatica. In the advanced stages, before too much damage has been done to the substance of the nerve and its branches, I have been able to accomplish surprising results in from ten to twenty treatments. And this being but the experience of others in the use of physical measures the conclusion is inevitable that in these newer methods, as compared with the older, we now have something better than "six months" in the treatment of sciatica.

Physical agents present a variety of methods for meeting the indication. In my hands, I obtain my best results in a combination of them. The methods employed in the two cases which I have cited were mechanical vibration, the static wave current, and high frequency sparks, in the order named.

What are the principles involved to meet the indication, the latter being, obviously, to liberate the nerve from its compression as early and as speedily as may be possible, before unnecessary or too great damage is done to its structure?

A brief summary of at least some of the principles as they are embodied in the various agents will prove, perhaps, not amiss.

Mechanical Vibration.—This agent teaches many interesting things in abnormal conditions of the body, and in this affection is valuable for the appreciation of the part the pyriformis muscle plays in its production, and affords efficient means for its control. Vibration reveals in a surprising manner the degree

of contraction which may occur in this muscle and also how extremely rebellious it may become in resisting the effort made to overcome it.

In such cases only thorough vibration will accomplish anything. At first the muscle will be found hard and unyielding and very soon it becomes evident that it is resisting the attack which is being made upon it, and in this state of apparent defiance it will hump up, so much so that in spite of the heavy pressure that is being exerted upon it you will feel the instrument with your hand being perceptibly lifted up, the resistance yielding only after a relentless attack, when the instrument will begin to sink, at times almost dropping suddenly to a surprising depth into the hip joint. Vibration should be continued at this point and evenly sustained until complete relaxation or inhibition of the muscle is secured, which will usually be manifested by the absence of pain.

Attention should now be directed to the spine and vibratory stimulation applied from below upwards, ascending as far as tender points reveal themselves.

In the use of so valuable an agent the method of application which I have described is permissible only in the early stages. In more advanced stages the procedure must be one of care and caution, as it is possible to do harm by irritating an already inflamed nerve structure.

Radiant Energy.—The application of heat in painful conditions of the body holds a time-honored place, and the hot water bottle has become a household necessity. Superheated dry air and the high candlepower incandescent lamp present heat in an intensified form, possessing anodyne properties to a remarkable degree.

The indication here calls for heat being directed to a deep-seated structure, and as the skin is a poor conductor of heat we must take advantage of physical laws in order that the resistance of the skin may be overcome. We, therefore, make use of radiant energy.

The agent which best meets the requirements is a high power lamp, such as the leucodescent, with which all of you are familiar. This lamp is admirably adapted for this purpose, as it gives the combined radiant energy of both heat and light, the latter of which is especially of value in conveying heat to a great depth, as rays of intensified light are readily transmitted and in their passage through the structures are being converted into heat by reason of the resistance which is met in the tissues.

The vasodilators being easily provoked into favoring a state of dilatation of the blood-vessels, as is seen in the flushing of the skin on even slight application of heat, we may look for something of the same nature taking place in deep-seated structures when heat is directed to them.

The action of heat then upon an engorged and stagnant muscle is both that of a stimulation of the circulation and a dilatation of the blood-vessels, and by determining a greater blood supply or flow, a flushing of these tissues takes place, permitting of the removal or washing away of irritating substances.

The action of a high power lamp of this character is applicable to any local inflammatory process or exudate which may exist anywhere in or about the course of the sciatic nerve, as its action favors and promotes the absorption of exudations. In other words, a better circulation tends to improve local nutrition, which, in turn, stimulates the processes of repair.

Static Electricity.—Probably the most potent and far reaching in effect in meeting the indication is static electricity. It may help some towards leading to a better comprehension of Franklinic electricity to call attention to the fact that it is capable of producing distinct and powerful mechanical effects upon tissues brought into immediate contact with it. For this purpose it is employed in the form of what has become known as the wave current, and sparks.

The wave current may be described, as it is to be adapted to the present indication, as a rhythmical mechanical movement of great penetrating power, each contraction being succeeded by a momentary period of rest or of relaxation, the whole movement occurring with a definite frequency. This current put in opposition to the passive contraction, or stasis, which is holding the pyriformis muscle captive, lays hold upon it with great power, and taking it up in its grasp a process of expression is set at work towards expelling and emptying the muscle of its foreign contents, of the infiltration fluids together with the products of irritation.

In order to make the attack still more effectual and complete in forcing the muscle into a state of relaxation the wave current should now be followed up with powerful static sparks; or high frequency sparks may be used as given from an inducto-resonator. Besides its ability to disperse local congestion and inflammation, the wave current has a notable systemic influence, setting up in the tissues of the body a gentle molecular vibratory action, stimulating the secretions and assisting in the elimination of toxic conditions. The patient subjected to this treatment will himself realize that a powerful force is being applied locally which is taking hold of the tissues reaching into the very depth of the hip joint, at the same time experiencing an appreciable effect of a genial warmth and glow of the body, oftentimes amounting to a perceptible perspiration, and, withal, imparting a feeling of well being.

The truth of all these facts, as well as the great amount of relief and comfort secured, become all the more impressive if the patient undergoing treatment should happen to be a physician himself who is suffering all the tortures of this disease. Some time since one of our estimable practitioners distressingly afflicted with this disease came to me for treatment in a state of desperation, after being helplessly confined to his bed for a period of three weeks, the result proving most gratifying to my patient and to myself.

The profession ought to know more about these mechanical effects. The unequaled results which they produce, for instance, upon the prostate gland, and upon the uterus in spasmodic or congestive dysmenorrhea, will prove a revelation; as will also the equally brilliant results in congestion of the liver, kidneys, and spleen; or, again, in an inflamed rheumatic joint, and allied conditions.

An increasing knowledge and an acquaintance with these effects will correct the very erroneous and mischievous position which many standing high in the profession are occupying with respect to this agent; and I do not doubt that the time is near at hand when the general subject of physical therapy must receive the investigation and just recognition which it merits.

Galvanism.—Although the newer modalities have largely supplanted the old galvanic and faradic currents, these have by no means become obsolete. Each modality seems to be able at one time or another to contribute something to the necessary stimulus of the reparative forces.

The wonderfully soothing and grateful flow of the continuous current as represented by galvanism has a distinctive feature in the treatment of the nerve

itself, and its judicious use in connection with the other modalities is an invaluable aid in the management of the chronic stages.

Roentgen Ray.—The *x*-ray is also to be mentioned as it is of value in stimulating the absorption of chronic indurations or scar tissue which may be causing pressure upon the nerve.

It is conceded that already the most important function of the medical profession is the prevention of disease rather than its cure, which function promises to mark the most remarkable era in the history of medical science.

In sciatica, as a neuritis, is presented the interesting proposition that it is capable of prevention as the means at our command are even now very sure of its control.

INTRAMURAL TRANSPLANTATION OF THE ROUND LIGAMENTS VERSUS ALEXANDER'S OPERATION OR VENTRO-SUSPENSIO-FIXATION OF THE UTERUS FOR RETROVERSIO-FLEXION.

By CHANNING W. BARRETT, M.D.,

CHICAGO, ILL.

GYNECOLOGIST TO CHICAGO POLICLINIC SCHOOL AND HOSPITAL, ADJUNCT PROFESSOR OF GYNECOLOGY, UNIVERSITY OF ILLINOIS MEDICAL SCHOOL; SURGEON AND GYNECOLOGIST MARION SIMS HOSPITAL; OBSTETRICIAN TO COOK COUNTY HOSPITAL.

Although displacements of the uterus and among them backward displacements are mentioned frequently in the writings of Hippocrates, Galen, Ætius, and other ancient writers, the true position and normal range of movability of this organ is of recent discovery. Even at the present time differences of opinion exist as to whether or not backward displacement of the fundus is of pathological consequence. Theilhauber, E. Schroeder, Pfannenstiel, Salin, Waite, and others claiming that the symptoms are due to the complications.

While I cannot go into a discussion of this question, I have well-grounded reasons for still holding to opinions previously expressed that retrodisplacements are deserving of treatment. To those, however, who consider uncomplicated retrodisplacements of no consequence, Alexander's operation is disposed of at once, for it is only in those cases that it is permissible.

Much has been written also upon the supports of the uterus. Many of our text books abound with phrases referring to "intraabdominal pressure" and "atmospheric pressure" as forces which maintain the normal position of the uterus. Repeatedly we read that if the fundus of the uterus is posterior to a vertical line drawn from the cervix intraabdominal pressure exerts itself upon the anterior wall of the uterus, crowding it backward. Nothing could be further from the truth. Intraabdominal pressure in itself exerts force equally in all directions. In the upper part of the abdomen we have intraabdominal pressure minus gravity, and in the lower part of the abdomen we have intraabdominal pressure plus gravity, hence the greater tendency to hernias through openings in the walls of the lower abdomen. Rectocele, cystocele, uterine prolapse and retrodisplacement are to a greater or less extent hernias through the pelvic floor. The uterus like all other intraabdominal organs is held in position by ligaments. These are suited to the weight of the uterus. They are not constructed to furnish the lower wall of the abdominal cavity and stand intraabdominal pressure plus gravity; this force is carried by the pelvic floor. If the pelvic floor is rendered useless this force falls upon the uterine ligaments and they sooner or later prove inadequate to the work thrown upon them. The uterus lying in the pelvis with the long axis of the body directed antero-posteriorly, parallel to the horizon, with the long axis of the cervix continuing backward and downward, is held in this position by means of its ligaments, the broad ligaments carrying a large portion of its weight, the sacrouterine ligaments holding the cervix upward and backward, and the round ligaments running outward, forward and upward, acting as guy ropes to direct the fundus forward. With each respiration, cough or jar the uterus moves according to the force exerted. Prolapse and retroversion are closely associated and are caused by anything which increases the weight of the uterus, or anything which decreases the carrying power of its supports, or anything which exerts force or makes traction in the wrong direction. Many cases of retrodisplacement may be corrected by proper treatment instituted within a short time after confinement or after a traumatism which acted as the etiological factor. But although the non-operative treatment should receive greater attention than the surgical gynecologist has been inclined to give it, yet the complications which bear the relation to the displacement of cause or effect or are coincident with it, or the long continuance of an uncomplicated retrodisplacement oftentimes makes operative measures necessary. The literature abounds with articles upon this subject and operations and technique are described to the confusion of the student. To undertake a detailed description of these operations is plainly not within the scope of this paper. I wish to deal more with the underlying principles of operative work.

The operations which have been most in the limelight have been (1) External shortening of the round ligaments, usually known as Alexander's operation or modifications thereof. (2) Ventro-suspensio-fixation with a false ligament. (3) Internal round ligament work. Other methods have had their exploitation, among which may be mentioned vaginal suspension, vaginal fixation, vaginal shortening of the round ligaments, but they require no serious consideration. Operations have had their rise and have maintained their foothold, as they followed certain essential principles, and they have had their decline as they failed to embrace other essential principles. An operation to hold its own at the present time 1. Must be safe; 2. Must be easy of execution; 3. Must allow of intraabdominal verification of the diagnosis when this is uncertain; 4. Must allow of correction of complications through the best possible opening when they exist; 5. Must create no false ligaments; 6. Must create no abnormal arrangement of natural ligaments; 7. Must use the best part of ligaments and throw out of use the poorest part of ligaments; 8. Must stand what Goldspohn has called the double test of pregnancy, that is, the operation must not interfere with pregnancy or complicate delivery, and the pregnancy must not interfere with the future success of the operation. An operation which meets these requirements will live, an operation which fails to meet them will die when pitted against an operation which meets them to a greater extent.

Vaginal operations, other than vaginal shortening of the sacrouterine ligaments, have practically all the above points against them and the latter operation has so many points against it that it has gained little ground. The Alexander operation was pro-

posed at a time when intraabdominal operating was dangerous, and therefore its strong feature, not opening the abdomen, commended it. It used the best part of the ligaments. But it was not simple, it was technical. Abdominal surgery at this time was in her swaddling clothes, fathered by a few men who were giants in the profession; they could master the technique by familiarity upon the cadaver. The operation was widely tested and then a reaction against it, for it had been used in cases where it was contraindicated. It makes no provision for inspection of the abdomen in the doubtful cases or the correction of complications when they exist. The greatest friends of the operation admit its narrow range of usefulness. Dunning shows that only 7.01 per cent. of cases are uncomplicated. Goldspohn, who has been a close student of round ligament surgery, insists upon the necessity of intraabdominal inspection and correction of complications in all cases of retrodisplacement. His bi-inguinal celiotomy for this purpose had a place in gynecological surgery when pitted against the unsurgical ventrosuspensio fixation, but it gave us at the best only limited opportunities for inspection and correction of complications. In the light of the above requirements the Alexander and the Goldspohn-Alexander operations must die or live a very narrow and lonely existence. During the last decade of the nineteenth century, ventro-suspensio-fixation, championed by such able men as Olshausen and Kelly, came into its own; in fact, its popularity was so great that it became a curse. It had to its credit the advantage of being simple and allowing inspection of the pelvic organs and correction of complications. Abdominal surgery had grown to be a giant octopus with arms outstretched to woo would-be surgeons in their swaddling clothes. The simplicity appealed to them. Difficult technique could not be learned upon the cadaver; there were not cadavers enough. The novice could open the abdomen and stitch the uterus to the abdominal wall even though he lacked skill at pelvic diagnosis or the ability to insert a pessary. Surgery that did not open the abdomen was tame and uninteresting. Every maverick of a uterus that could not give an account of its slightest wandering was branded with the curse of an extra ligament or two. But although the incision for this operation gave the best opening for doing work, and although it made an easy operation for the tired surgeon, it ignored most of the above-named essentials for a good operation. Theoretically, then, its passing was to be expected and, in this instance, the expected happened. In the obstetrical and gynecological section of the Boston meeting of the American Medical Association, the subject came up for discussion and not one voice was raised in favor of ventro-suspension or fixation. Among the leaders in this line of work then ventro-suspensio-fixation is dead. In asking an occasional operator what he does with retrodisplacement, I have received the answer "I do the thing that I know how to do, ventrosuspension," and so the sins of the "fathers" in surgery will be visited upon their children until the third and fourth generation. Why should it not be used? It creates false ligaments which neither grow during pregnancy nor involute thereafter. There is no certainty as to the size of the resulting ligament, and therefore no reliability as to results. Transperitoneal ligaments are created, which may entangle bowels and omentum. The permanency of the operation depends upon the formation of a strong ligament that will not stretch extensively, yet these are the things which render it dangerous if pregnancy takes place. F. Martin collected with Dorland's 179 cases, 425 cases of pregnancy following ventral fixations and suspensions. Of these 425 cases 96 cases were complicated during gestation, and 116 were complicated during labor. Nine versions were necessary, fifteen forceps deliveries, three placental retentions, three postpartem hemorrhages, twenty-four abortions (four of which were produced), eight cesarean sections, one ruptured uterus, one inversion of uterus with death of mother, nine fetal deaths besides the abortions, seven maternal deaths. Ingalls, formerly an advocate of ventrosuspension, has changed his views as a result of his observations, in three cases of dystocia in which two patients suffered rupture of the uterus and one case required version in which death of the child resulted. Hurdon reports two cases in which it became necessary to open the abdomen and sever a ventrofixation ligament because of backward and upward displacement of the cervix. Lynch in a careful study of cesarean section and dystocia following ventrofixation and suspension reports two cases of dystocia and collects 21 cesarean sections. He also mentions having observed reports of 10 cases of rupture of the uterus. Of the two cases which he reports one had cesarean section with delivery of twins, the mother dying on the sixth day. In the other case version and extraction was practised with difficulty and nine weeks later celectomy was performed to obliterate the adhesions which caused persistent pain. I have operated upon one case not pregnant for the relief of troublesome pulling of the uterus upon the abdominal wall. I also lost Mrs. M. at second delivery after a ventrosuspension, from a severe postpartum hemorrhage, controlled, but returning several hours after confinement. A marked postpartum hemorrhage followed the first delivery after the ventrosuspension, but from this the patient made a good recovery. If further evidence is needed to convince the skeptic of the inadvisability of performing ventrofixation operations it is not wanting in literature as shown by Noble, Halban, Lynch, Dorland, Goldspohn, and many others.

Some of the difficulties encountered are: Retraction of scar, severe pain in abdomen, abortion and premature labor, posterior ascent of cervix, tumor mass caused by thickening of anterior uterine wall, excessive thinning of posterior wall, hyperemesis, prolongation of pregnancy, inertia, dystocia, malpresentation, rupture of scars, rupture of uterus, retained placentæ, post-partum hemorrhages, etc. In the non-pregnant relapses from inefficient adhesion, pain from too firm adhesions, obstruction of bowels, entangling of omentum tubes and ovaries around the ligament. Suspension has been praised while fixation has been condemned, but Kelly, Hurdon, Lynch, and many others emphasize the fact that intended suspension sometimes results in a fixation. The Alexander operation has points of great advantage in those cases in which it is indicated but they are few. The ventral suspension allows of correction of complications but causes other complications that are dangerous. To avoid these dangers in complicated cases many have devised means for using the round ligaments when opening the abdomen. These may properly be divided into two classes, those which employ the inner, strong part of the ligament, and those which employ the outer, weak part of the ligament. The latter do not meet the requirements for a reliable operation and place a confidence in this part of the ligament not warranted by its size and strength. The former operations may again be divided into those which reach the ligament through extensive and tedious dissec-

ton from the abdominal incision and those which reach the ligament in the abdomen where it is easily picked up.

Edebohls, Polk, and others have operated through a median incision to correct complications and then have made the inguinal incisions to shorten the ligaments. This and the operations of Noble, Barth, Sandberg and Pinkham illustrate the length to which operators will go to use the round ligament. When one is through with the intraabdominal work he is just beginning a very tedious operation. Their technicalities discourage their use. The operations which employ the round ligament and secure them within the abdomen had their beginning with Olshausen sewing the round ligament, close to the uterus to the abdominal wall. Others carried the suture in the round ligament a little further out. Carl Beck, of New York, freed the round ligament from its natural course, and sewed it into the abdominal incision, making round ligament ventrosuspension. Ferguson made a poorer opening for doing work, but a better operation for supporting the uterus in his planting the cut ends of the round ligament into the abdominal incisions, one inch lateral to the median line. Gilliam made a decided improvement upon this when he made a median incision and brought loops of the round ligaments through a puncture opening to the right and left of the median line. This was still ventrosuspension and furnished two transperitoneal ligaments which might entangle bowel, omentum, tubes, or ovaries, and three small openings from the abdominal cavity into the uterovesical space, through which a bowel might become herniated. In view of the many evils arising from direct uteroventral suspension the above objections were urged strongly against this operation. Ferguson proposed obliterating the two side openings with purse-string sutures. Simpson proposed to obviate this by running the ligament forward over the bladder, but under the peritoneum to the abdominal wall. We were looking for something that could be done through a median incision and yet use the best part of the round ligament so placed as to create no complications. It occurred to me that by going through the median line to do work in the abdomen and pick up the ligaments, I could then carry them through the internal ring and fasten them at some point without tedious dissection, as was done by Edebohls' Alexander operation following celectomy. After considering the many ways in which the ligament could be dealt with such as a puncture over the internal ring, tunneling over the aponeurosis, etc., the most feasible plan seemed to be to pass a curved ligature carrier under the aponeurosis to the internal ring and there enter the abdomen and secure the silk ligature which had been previously placed upon the round ligament two-thirds of the distance from the uterus to the internal ring. The forceps are then withdrawn and along with them the silk loop, and with this the loop of round ligament, which is sewed to the under side of the aponeurosis over the rectus muscle, and then if long enough it is sewed to the loop on the opposite side. We now have the ligament running from the uterus to the internal ring, then under the aponeurosis over the rectus muscle to or near the median line where it is sewed, then back to the internal ring, then through its normal course to the labium. It is shortened by the distance of its excursion inward and back to the internal ring. This operation which I later termed *intramural transplantation of the round ligaments,* I first performed in November, 1903. I taught it in my post-graduate and under-graduate work, but postponed its publication until I had given it a trial on numbers of cases for several months. In the spring of 1905, having had it under observation for eighteen months, I presented it in April before the Kalamazoo Academy of Medicine, in May before the Detroit Alumni Association, in June before the Chicago Medical Society, and later before other societies. My first publication, except by reference, was in *Surgery, Gynecology and Obstetrics,* November, 1905. This explanation would not be necessary were it not for a much published article by Stuart McGuire in 1906 and 1907 in which he describes an operation of very similar technique seen at a clinic and in which he was innocent of the work done by others, as shown in literature.

This operation has been combined with most other gynecological operations where the uterus is left in. In many cases a curettage, amputation of the cervix, perineorrhaphy, anterior colporrhapy, hemorrhoidectomy, celiotomy, breaking up adhesions, cöpherectomy, salpingectomy, resection of an ovary, appendectomy, and myomectomy. In one case an extrauterine gestation sac was removed with this operation following; in another case reported the four months gravid uterus was freed from adhesions, the left tube and ovary were removed, and then the intramural transplantation was done. This patient went to term, had a normal delivery, and the uterus was found in good position afterward. Three other cases are known to have been pregnant. One produced an abortion, the other two went to term. One of these became a Christian Scientist and has not since been under observation. The other had a normal delivery and the uterus remained in perfect position after childbirth. Statistics regarding pregnancy and its effects upon the operation are abundant in the Alexander operation, for I hold that the placing of the ligament is such that anything that may be said of the Alexander operation may be said of this. In the four years' experience with the operation I have known of only one case in which the uterus was not held in position. In this case adhesions were extensive, before the operation. Adhesions between the posterior surface of the uterus and the bowel seem to have taken place, pulling the uterus slightly backward. One of the sequelæ which seemed possible was an occasional hernia from disturbances at the internal ring and an occasional hematoma from trauma of blood-vessels at the ring. Neither of these accidents have been observed. In my early work I think there was a tendency to draw the ligaments too tight as an occasional case would complain of pulling for some time afterward. The operation is not so easily understood as the ventrosuspension, but it is much less technical than the operations which search for ligaments outside the abdomen.

In some cases I have made a two and one-half inch incision transversely down to the aponeurosis of the external oblique, then a median longitudinal incision to do the work in the abdomen, then the ligature carrier was pushed through the aponeurosis at the outer ends of this transverse incision, and was carried through the internal ring to pick up the control silk on the round ligament. This, while it makes a splendid operation, is only advisable when the complications are slight. The median incision through all the layers is preferable for severe complications. In addition to the round ligament work it has seemed best at times to shorten the sacrouterine ligaments. We should remember that the work of ligaments is to carry the uterus; they are

not intended to do the work of the pelvic floor, and this latter structure should be repaired if inefficient.

This operation makes the most anatomically perfect operation which has yet been proposed which does not require tedious dissection to find the ligament, and has the distinctive feature of having the ligament leave the abdomen at the proper place—the internal ring. We cannot hope in our operative work to improve upon the normal condition; no operation can anchor the ligament farther out or a less distance and be quite as right.

In conclusion I would say:

1. Alexander's operation fails because most cases of retrodisplacement are complicated.

2. An operation to be widely useful must open the abdomen for inspection and correction of complications.

3. It should be capable of being combined with the best incision for doing work.

4. It must not create false ligaments which will not evolute during pregnancy and involute thereafter.

5. There must be no abnormal arrangement of natural ligaments which allows them to run transperitoneally.

6. When the round ligaments are employed the inner, stronger portion of the ligament should be chosen.

7. An operation for retrodisplacement must often be performed after much other operating, and so should not offer any tedious technicality such as is found in the external search for the ligaments.

8. My internal inguinal shortening and transplantation of the ligaments through the abdominal wall is again submitted for comparison with external shortening of the ligaments, or ventrosuspension operations as one seeming to meet the essential requirements of an operation for retrodisplacements.

100 State Street.

AUTOINTOXICATION AND INDICANURIA.

By ALBERT ABRAMS, A.M., M.D.,

SAN FRANCISCO.

This important subject has been exhaustively discussed by William H. Porter in the Medical Record,[1] but there are additional facts concerning it which demand succinct citation. The writer has endeavored to prove in his work on "Splanchnic Neurasthenia" that the essential condition present in this affection is intraabdominal venous congestion superinduced by insufficiency of the splanchnic vasomotor mechanism, and that the neurasthenic symptoms resulting therefrom may be corrected by certain abdominal physical exercises, which have for their object the relief of the intraabdominal congestion.

Among the reviews of the author's book in question, the refrain of one was that the good results achieved by treatment could only be attributed to suggestion. The latter is a portentous word and signifies much or nothing, but usually, the latter. It is, unfortunately, too often employed by the theorist as a vehicle for his oracular pronunciamentos. Among the symptoms of splanchnic neurasthenia, congestion and enlargement of the liver are invariable, and after respiratory massage of the organ, even after a single *séance* of massage, the symptoms in question evanesce. Thus, one is in possession of an objective sign that positively excludes suggestion as a contributory factor. There is another sign, however, to which I will presently direct attention. The hepatic signs to which reference has already been made are equally characteristic of intestinal autointoxication and often constitute the only symptoms of the latter affection.

Intestinal autointoxication, as we now comprehend it, may be briefly summarized as follows: During digestion, a number of poisons or enterotoxins are manufactured as a result of putrefaction of albuminoid food in the intestines. These enterotoxins attain the liver by way of the enterohepatic circulation where they are made innocuous. From the liver they pass into the general circulation and are excreted in the urine. If albuminoid putrefaction is excessive, or if the liver and kidneys (notably the former), prove inadequate in either neutralizing or excreting the poisons, autointoxication ensues. Intoxication is expressed by a motley group of symptoms which often parade under the equivocal designation, neurasthenia. Now, this conception of intestinal autointoxication is only partially correct. While the usual enterotoxins are bacterial products, there are also poisonous albumoses, *i. e.* intermediate products manufactured in the digestion of albuminous foodstuffs. It is well known that when peptones and albumoses (normal products of digestion) are injected directly into the blood, they are poisonous and even fatal in their effects. Falloise[2] has recently had an excellent opportunity of studying this subject in a patient with a fistula of the small intestine. He concludes that albuminoid-putrefaction is not the only process concerned in autointoxication, and that an aqueous extract of the contents of the small intestine is infinitely more toxic than an extract made from the contents of the large intestine. Hence, if we accept the prevailing opinion that putrefaction of the albuminous molecule is limited in the norm to the large intestine, factors other than putrefaction of the albuminous molecule must be concerned in intestinal autointoxication.

Contrary to current belief, I have found that, in those suffering from self-poisoning, diarrhea, or at any rate, looseness of the bowels prevails rather than constipation, and it appears as if this were a compensatory attempt on the part of the organism to rid itself of noxious products. Strassburger has shown that retarded bowel-action rather indicates diminished products of decomposition which normally stimulate the action of the intestines. If one were guided in the diagnosis of autointoxication by the statements of the patient, the condition would rarely be recognized. The fact is, the patients infrequently complain of symptoms of indigestion. It is only in aggravated cases that one encounters the conventional symptoms of dyspepsia. In most instances, nervous symptoms precede the local signs of indigestion.

Another supposed classical symptom of the affection is indicanuria, yet my experience shows that it is comparatively infrequent. I have shown[3] that the application of the sinusoidal current to the abdomen will promote the excretion of indican in the urine and that its presence in the urine may be demonstrated after a single *séance* lasting fifteen minutes, even though previously absent. Naturally the urine must be voided before and after the application of the current and the specimens compared after examination is made for indican. For the examination of the latter I prefer the simple test recommended by Porter.[4]

I have shown that abdominal massage properly executed will likewise augment the excretion of indican in the urine. More recently I have found that respiratory massage of the liver will also augment the excretion of indican even more pronouncedly than massage or sinusoidalization of the abdomen.

One knows that in correct abdominal breathing, the liver is rhythmically compressed between the diaphragm and the anterior abdominal wall. We are able to duplicate and accentuate physiological compression of the liver by substituting the fingers for the anterior abdominal wall, the resistance of which in ordinary breathing is but feebly expressed. The patient is placed in the recumbent posture with the thighs flexed on the abdomen. The fingers are then passed successively under the ribs in the axillary, mammary, and parasternal lines respectively and in the median line. During the time the patient takes a forced inspiration (with mouth open), pressure is executed backwards (the fingers remaining fixed) as though an effort were made to prevent the liver from descending. After this manner, the patient takes at least one hundred forced respirations. Naturally such massage must be interrupted from time to time to avoid exhaustion of the subject. The most constant point of hepatic tenderness in splanchnic neurasthenia and autointoxication is midway between the tip of the ensiform cartilage and the umbilicus. Pressure is made with the patient leaning forward at the end of a forced inspiration. Now, it will be found, that after a single *séance* of respiratory massage, the hepatic tenderness is either diminished or disappears, and indican previously absent in the urine can now be demonstrated. The diagnosis of the affections in question may be made by the results of respiratory massage.

Primarily the quantity of indican in the urine is always increased over the normal in autointoxication, but what constitutes the normal is indicated by observation of a number of patients. From day to day the excretion of indican diminishes after massage and with such diminution there is a corresponding improvement in the well-being of the individual. If, notwithstanding the foregoing, there is no abatement of the symptoms, there must be an error in the diagnosis. It is naturally assumed that the diet must be the same during the course of treatment, for one knows that the character of the diet influences indicanogenesis. Thus animal proteids demonstrate a greater tendency to putrefactive fermentation than the vegetable class. In many instances one finds an augmentation of urea in the urine after respiratory massage, and no doubt an accurate analysis will show the presence of toxins. In several instances I was able to demonstrate the presence of bilirubin in the urine after hepatic massage. One cannot ignore an insufficient splanchnic vasomotor mechanism in the treatment of autointoxication, for a disregard of the latter factor nullifies our therapeutic efforts which are often conceded to be impuissant in this condition.

Food as a factor in the treatment of autointoxication is a much abused commodity. Some one has observed that the ultimate trend of the physician was to prove that even food was poisonous and what has been suggested as a facetious prognostication, appears to have been endowed with reality, when one seriously contemplates the endeavors of dietetic revolutionists. Many dietetic vagaries are as consistent as the perfervid plea of the poet Shelley, who wanted us to become vegetarians and marry our sisters. By opposing alimentary insufficiency we possess a formidable weapon in immunizing the tissues against interminable dietetic insults. One must not forget that there is such a condition as "indigestion toxemia," due either to an excessive production of poisons or to enfeeblement of the defenses. Thus there is an hepatic as well as a gastric and intestinal dyspepsia and the liver dare not be ignored even in the treatment of an ailment so plebeian as dyspepsia.

Intestinal asepsis is, in my experience, a purely theoretic conception which is rarely realized in practice. Intestinal antisepsis is difficult if not impossible for the following reasons: (1) An antiseptic strong enough to destroy germs is equally destructive to the intestinal mucosa. (2) Germicides will destroy the innocent germs which are concerned in digestion. (3) Germicides are rapidly absorbed or are made chemically inert. Recourse is also had to purgatives but they often accentuate the symptoms of autointoxication because they concentrate the poisons already absorbed and remove the intestinal epithelium and mucus which practically act as barriers against the absorption of enterotoxins. We have discarded the swab in infectious diseases of the throat, for the reason that it mechanically injures the membrane of the throat and thus opens up new portals of infection. In this sense, the purgative is essentially an intestinal swab.

Diseases of Doctors.—The *British Medical Journal* says that a comparison of tables compiled by statisticians in different countries gives doctors an average of 57 years at death. Setting aside affections due to exposure and infection, the practice of medicine levies a disproportionate tribute from its professors in the form of diseases of the cardiovascular and nervous systems. Angina pectoris has been called the "doctor's disease"; neurasthenia deserves to be ranked in the same category, and severer forms of neurosis are common.

Polisarcia and Fatty Heart.—Giovanni Galli considers whether there may be a hereditary element in abnormal obesity, the patient inheriting a diminished power of oxidation with an especial tendency to deposit fat in the cells. Some persons who have undergone amputations, women at the menopause, and persons with genital stimuli are liable to deposit fat in the tissues. The abuse of foods, wine, and alcohol has the same result. Such persons always have disturbances of the circulation. But fatty heart does not always accompany obesity. Fat becomes deposited in the cells of the body, and they undergo degeneration. It is also deposited in an extracellular manner. The left ventricle is most frequently affected by fatty degeneration, the tissue taking on a yellowish color. The ventricle becomes dilated and the valves insufficient. Rupture may even occur. Atheroma of the coronary arteries is not infrequent. Pain in the region of the heart is not rare, irradiating to the left arm. Treatment is mainly prophylactic, including changes in diet, such as to reduce fat with baths and graduated exercise.—*Gazzetta Medica di Roma.*

Resuscitation by Cardiac Massage.—At a recent meeting of the Leeds and West Riding Medico-Chirurgical Society, J. F. Dobson read notes of a successful case of resuscitation of a child apparently dead from chloroform syncope. The abdomen was opened and the peritoneum stripped off the diaphragm and the heart, motionless and flaccid, was massaged through the diaphragm until beating recommenced. Prof. A. S. F. Grünbaum, in discussing the case, drew attention to the length of time during which a child's heart remained excitable. He had seen in two cases at post-mortem examinations hearts removed six and ten hours after death prove excitable when placed under suitable conditions.—*The Lancet.*

THE WORK OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

THE annual report of the Surgeon-General of the U. S. Public Health and Marine-Hospital Service, recently issued, is an interesting document and an enlightening one to those who think that the National Government, in the absence of a Department of Public Health with a cabinet officer at its head, is doing little to safeguard the health of the country. The Bureau of Public Health of the Treasury Department, adapted from the century old Marine-Hospital Service, has now been in existence nearly six years, and the work it has accomplished in that time has fully justified its creation. The work of the Bureau in relation to public health is practically unlimited. It has charge of the quarantine service over the whole of the Pacific coast, the Gulf coast with the exception of Texas, the Atlantic coast with the exception of Baltimore, New York, Boston, and a few of the minor neighboring ports, and in the Philippines. In connection with the quarantine service medical officers of the Bureau are stationed at ten of the chief fruit ports in Central and South America, at the principal ports of Japan and China, at Calcutta, and at Naples, whose duty it is to insure care in the sanitation of the vessels sailing for the United States and also to examine departing emigrants. An interesting feature of the Service, to which this report calls attention, is its detail of officers to assist other Departments of the Government and to assume sanitary control in case of emergency. Thus three surgeons have been assigned to duty with the Isthmian Canal Commission, one has served as a member of the hookworm commission in Porto Rico, Surgeon Victor G. Heiser is in charge of national quarantine in the Philippines and has also for over two years been director of health in the Islands; the plague situation in San Francisco and elsewhere on the Pacific coast is in charge of officers of the Service; the Bureau is investigating leprosy at Molokai, Hawaii, and is erecting buildings for the station there; and the sanitation of the Jamestown Exposition was also made a part of the work of the Bureau.

During the year investigations of the causes of typhoid fever have been made in Washington, in Savannah, and in Charlotte, N. C. A very important investigation, to which we have referred in a recent issue, was that of the milk supply of Washington. The report of this inquiry is one of the most important documents relating to public health ever issued by the National Government. Much of the work of this investigation was conducted in the Hygienic Laboratory of the Bureau, which is an institution of great merit. The scientific work of the Laboratory, as expressed in the bulletins issued therefrom, has been received with interest and commendation by sanitarians and investigators everywhere and compares favorably with that of the other and older institutes for scientific research throughout the world. A new building, doubling the capacity of the laboratory, will be erected this year. Another important work of the Health Service is the supervision of the manufacture of vaccines, serums, etc. Each and every lot of vaccine virus sold by permission of the Service is examined bacteriologically to determine its freedom from tetanus and other pathogenic microorganisms, and in addition, both vaccine virus and therapeutic serums are purchased from time to time in the open market in different parts of the country, and examined. Some time ago a standard was prepared in the Hygienic Laboratory for measuring the units of diphtheria antitoxin, and recently one has also been devised for measuring the strength of tetanus antitoxin. In addition to this work of supervision of antitoxic serums and vaccines, the Surgeon-General recommends that the examination from a public-health standpoint of new and nonpharmacopeial disinfectants and medical preparations be made one of the functions of the laboratory. A good deal of this work has already been done, but it is believed that much more should be done there in the future. An examination of some of these products is conducted unofficially by the Council on Pharmacy and Chemistry of the American Medical Association, but Surgeon-General Wyman holds that such work is incumbent on the Public Health Service in accordance with the law establishing the Hygienic Laboratory. Such an investigation, conducted by a Bureau of the National Government, would compel the respect of the entire profession, and its findings would be marked by an authority which those of the Council on Pharmacy and Chemistry cannot command.

The question of the creation of a new executive department of the National Government and the addition of another member of the Cabinet in the person of a Secretary of Public Health is one which is legitimately open to discussion. While admitting the weight of some of the arguments against such a measure, we nevertheless believe it would be a step in the right direction, economically as well as in the actual saving of life and health. There is perhaps a vague recognition of the economical side of sanitary work in the fact that the Public Health Service is a Bureau of the Treasury Department, but this is only one, and the less important side. An independent Secretary with his greater authority and freedom of action could accomplish much more than the mere head of a Bureau, and the existence of a separate Department would emphasize the importance of sanitary work, would give it greater dignity in the estimation of the community, and would vastly increase its utility and power for good. But Congress is against it and the President is against it, so for the present there is no hope of the establishment of such a governmental department. When, however, the time comes for this recognition of the importance of safe-

guarding the health of the people, and come it must, the department will be found already organized; the verbal changes of Bureau to Department and of Surgeon-General to Secretary will be all that is necessary to create a full-fledged and thoroughly efficient Department of Public Health.

THE LIMITATIONS OF THE NEWER TUBERCULIN REACTIONS.

The enthusiasm that has greeted the advent of the recent cutaneous and ophthalmic methods for the early diagnosis of tuberculosis has reached the stage when it must needs be tempered by the searching criticism of experience. That there has been an urgent need for a simple clinical test for the detection of incipient tuberculosis is amply evidenced by the widespread adoption of the methods of von Pirquet and Calmette. The literature, particularly of Germany and France, is teeming with reports, some favorable, and some unfavorable, upon the real practical utility of these newer diagnostic resources. The comparative value of the various reactions in children has received the attention of F. Reuschel (*Münchener medizinische Wochenschrift*, February 18, 1908). This observer has found that the original hypodermic method of Koch is not trustworthy in cases of severe phthisis and in acute miliary tuberculosis, and cites the observations of Köhler and Behr that 25 per cent. of normal individuals react with fever to the hypodermic injection of tuberculin, this febrile response being attributed to hysteria. Of far greater value than the constitutional symptoms of the subcutaneous injection of tuberculin has been found the local phenomena in the region of the needle puncture. This, the so-called "puncture reaction" ("stichreaction" of Escherich), consists of a sharply circumscribed red area of infiltration, edema, and pain surrounding the site of puncture. Reuschel has found that the puncture reaction was constant in cases of tuberculosis, and that it was present in cases that did not react with fever. He believes that the puncture reaction is particularly available for suspicious cases that are regularly "running a temperature," in which, of course, the febrile response to tuberculin would be entirely masked. On the other hand, a febrile response to tuberculin, in the absence of the puncture reaction, is not to be regarded as an indication of the presence of tuberculosis. As regards the cutaneous reaction of von Pirquet, Reuschel found that it was convenient and adapted for general use in practice: when positive, it indicated tuberculosis, but its negative occurrence after a single trial gave no decisive answer. In the latter case, the performance of the puncture reaction would clear up the difficulty. Both methods were not to rival the older method of Koch, but all three were to supplement one another. It was still to be investigated whether the local sensitization revealed by the newer methods indicated the presence of antibodies of tuberculosis, which this observer doubted, or whether it revealed the presence of antibodies to the proteid substances of the bouillon.

Prof. E. Feer (*Münchener medizinische Wochenschrift*, January 7, 1908) finds in the von Pirquet reaction a valuable aid in the diagnosis of tuberculosis in children. But the intensity of the reaction is not proportionate to the extent of the lesion, and while the positive reaction indicates the presence of tuberculosis, a negative result does not exclude this disease, for in the presence of cachexia, miliary tuberculosis, and meningitis, there is no cutaneous reaction. In children the vaccination test is considered preferable to the ophthalmous reaction, which is absolutely contraindicated in scrofulous children, on account of the frequent occurrence of severe conjunctival irritation and phlyctenulæ following the instillation of tuberculin. The value of the cutaneous reaction diminishes as age advances, for in older children and adults, apparently in perfect health, some of whom are possibly carriers of small, inactive tuberculous foci, in the majority of cases there is a positive reaction to both the cutaneous and conjunctival tests. Thus, von Pirquet has found that in individuals from 10 to 14 years of age, 55 per cent., and in adults, 90 per cent., react positively to both tests. Feer found that between the ages of 10 and 15 years, 35 per cent. react positively. Thus at this period of life, the positive reaction is of limited significance, while to the negative response a greater value must be accorded. The rule is laid down that the nearer one approaches the nursing period, the more the positive reaction is apt to indicate the presence of tuberculosis.

A careful study of the comparative values of the skin and ophthalmic reactions was made by Carlos Maunini (*Münchener medizinische Wochenschrift*, December 24, 1907). He found that both reactions occurred with great constancy in all cases of tuberculosis, excepting those that were far advanced, and that although it was quite probable that the reactions were specific, this had not yet been proved. In individuals in whom there was no reason to suspect tuberculosis, a positive cutaneous reaction occurred six times as frequently as the ophthalmic. Assuming that the reactions were specific, this contradiction was explained on the hypothesis that the ophthalmic reaction revealed an active tuberculosis, while the cutaneous reaction revealed a latent focus.

That the ophthalmic reaction is not altogether a harmless procedure is indicated by the experience of Wiens and Gunther (*Münchener medizinische Wochenschrift*, December 24, 1907). These observers found that the instillation of a 1 per cent. solution of tuberculin in a number of cases caused severe ocular disturbances, in some lasting for several months. These severe reactions occasionally occurred in patients in whom there was not the slightest evidence of tuberculosis. It is concluded that the Calmette reaction is by no means as harmless as has been thought, and is to be absolutely excluded in all cases of chronic conjunctivitis, no matter how mild.

In 17 positive cases of tuberculosis in which the diagnosis was confirmed by the presence of bacilli in the sputum, C. Kleinberger (*Münchener medizinische Wochenschrift*, December 24, 1907) found that 7 cases did not react at all, and that 2 reacted doubtfully, to the ophthalmic test. A positive reaction following a second instillation into the conjunctival sac was of no clinical value, for in 46 cases in which tuberculosis was clinically excluded, and in which

the first instillation was followed by a negative or by a mere trace of a positive reaction, a second instillation was followed by a markedly positive reaction in 36 cases, which was 78 per cent. of the entire number. This percentage was certainly too large to be explained on the basis of a latent tuberculosis. It simply indicated that the conjunctiva was sensitized by the first instillation. This observation has more recently been confirmed by M. J. Rosenau and J. F. Anderson (*Journal of the American Medical Association,* March 21, 1908), who found that in twelve normal individuals in whom the first instillation of tuberculin was negative, the second instillation after an interval of 51 days was followed by a positive result. These experiences prove that no reliance can be placed on the result following a second instillation of tuberculin.

There have been a number of investigations whose results argue against the specific nature of the ophthalmic reaction. Thos. L. Blum (*Münchener medizinische Wochenschrift,* January 14, 1908 has found a positive reaction in 31 out of 188 cases which were clinically nontuberculous, the positive reaction occurring in cases such as emphysema, chronic bronchitis, tabes dorsalis, apoplexy, sciatica, severe anemia, enteritis, pleurisy, and diabetes. Similarly, S. Cohn (*Berliner klinische Wochenschrift,* November 25, 1907) found that 8 out of 12 typhoid patients presented the specific reaction. F. Levy (*Deutsche medizinische Wochenschrift,* January 16, 1908) obtained a positive reaction in 2.5 per cent. of 235 nontuberculous patients, while P. Eisen (*Beiträge zur Klinik der Tuberculose,* Vol. VIII, No. 4) obtained a positive reaction in 31 per cent. of 17 patients with various nontuberculous affections. G. Serafini (*Giornale della R. Accaddemia di Medicina, Turin,* November, 1907) found that the ocular reaction was not conclusive in cases of tuberculous processes in the bones and joints. The reaction was positive in certain gonorrheal articular affections, as well as in several cases of senile and other nontuberculous bone affections. A. Plehn (*Deutsche medizinische Wochenschrift,* February 20, 1908) obtained a positive reaction in 2 out of 5 cases of typhoid; in 2 out of 5 patients with scarlet fever; in 6 out of 12 with articular rheumatism; in 3 out of 6 with acute bronchitis; and in 3 of enteritis. In none was there any tuberculosis.

It cannot be denied that the cutaneous tuberculin reaction is a valuable addition to our diagnostic armamentarium, furnishing strong presumptive evidence of the presence in the body of some tuberculous focus, either healed or active, but reliable only when considered in connection with other signs of the disease. The positive reaction should be interpreted in the light of the numerous recent investigations of the limitations of and the possible erroneous conclusions that might be derived from it. In addition to its diagnostic value, this reaction bids fair to throw considerable light upon the problem of immunity in tuberculosis. The ophthalmic reaction, however, is one that should be employed with extreme caution, for the procedure is by no means as harmless as was at first supposed, and many cases are now on record of corneal ulceration and other untoward results of the tuberculin instillations.

OPERATIVE TREATMENT OF HIRSCHSPRUNG'S DISEASE.

This disease, megacolon, or congenital dilatation of the colon, though easily diagnosed, is of poor prognosis, hence any method of treatment that offers a prospect of success is worthy of serious consideration. In the *Deutsche Zeitschrift für Chirurgie,* Vol. 90, Nos. 4, 5 and 6, Ito and Soyesima recently published the history of a boy suffering from this disease and discussed the treatment in detail. Their patient, fourteen years old, had suffered from nocturnal incontinence of feces since birth, the abdomen was distended, the umbilicus flat, and there was visible peristalsis. Fluid was absent, but the left half of the abdomen, from just above the umbilicus down to the true pelvis, was occupied by a doughy, slightly movable mass, with a dull tympanic note. A rectal tube inserted into the anus entered the mass which was found to consist of soft feces. As medical treatment was of no avail they decided to operate. At operation the descending colon and sigmoid were found greatly dilated, their wall was thickened, their mesentery normal, and strictures were absent. They made an anastomosis between the ileum and upper part of the rectum and then did a coliplication for a distance of twenty centimeters above the point of anastomosis, thus reducing the width of the intestine from eleven to five centimeters. After operation the boy had occasional voluntary movements but the fecal tumor returned. They operated a second time and divided the ileum just beyond the point of anastomosis thus entirely excluding the colon from the intestinal tract. The boy made an uneventful recovery and was cured.

Ito and Soyesima do not say that this disease should be treated only surgically, nor of course do they hold as some observers that it should never be treated surgically. They believe in surgical treatment when massage, electricity, diet, and colon irrigations have been of no avail. As regards the surgical procedure of choice it may be said that nearly all the possible intestinal operations have been tried. Colotomy with immediate closure or puncture of the dilated intestine gives only temporary results. Coliplication and coloplastic operations are rarely followed by any improvement, never by cure. Enteroanastomosis does not always give good results as we see in the above case. However, Ito strongly recommends enteroanastomosis with exclusion of the diseased intestine from the tract, and the result obtained in his case seems to warrant his recommendation. The only other operation which is effectual is resection of the dilated portion of the intestine; this is a radical measure and is accompanied by much greater danger and should therefore be performed only when Ito's method is impossible.

The Treatment of Diphtheria with Pyocyanase.

The gratifying results obtained by von Emmerich in the treatment of diphtheria by means of pyocyanase, a product formed in cultures of the *Bacillus pyocyaneus,* have been corroborated by several other observers, who have stated that the local application of the agent to the diseased surfaces was followed by the disappearance of the membrane,

diminution in the oral fetor, and improvement in the general condition. It is a difficult question, however, to determine the efficacy of a new remedy in a malady like diphtheria for which a satisfactory mode of treatment already exists, for in all severe cases, of course, serum must in fairness to the patient be used in addition to the pyocyanase. Schlippe (*Deutsche Medizinische Wochenschrift*, April 2, 1908) administered the latter alone in six mild cases, with good results, but in six others he was obliged to give serum also. Twenty-four other patients received both remedies from the start. Experiments *in vitro* with diphtheritic membrane showed that the pyocyanase was actually lytic for this material, but on the result of his clinical observations Schlippe is not inclined to estimate its therapeutic value very highly. It should not be used except as an adjunct to the serum treatment, but would appear to have distinct value in cases in which there is excessive membrane formation. In the severe examples of septic diphtheria it is not particularly effective and it does not cause the destruction of all the diphtheria bacilli present in the throat and nasal passages.

The Physiological Action of the Roentgen Rays.

That the Roentgen rays possess the capacity to influence cellular activities has been clearly demonstrated, though the manner in which this effect is produced is still uncertain. A number of observers have agreed with Schwarz's view that the fundamental process is a breaking down of lecithin, a theory founded on the observation that egg yolk after radiation decomposed more quickly than before. Richter and Gerhartz (*Berliner klinische Wochenschrift, March* 30, 1908) have investigated the problem by exposing adrenalin to radiation and then testing its activity as regards blood pressure elevation and sugar excretion. Both of these properties, but especially the former, were considerably reduced by the treatment, the capacity to elevate the blood-pressure on injection into animals being partly or entirely lost. Further experiments were made on various ferments, including lab ferment, yeast, pepsin, pancreatin and others, with the result that the rays appeared to be without effect on the specific properties of these substances. The authors, therefore, conclude that theories seeking to explain the action of radium or Roentgen rays through a modification of fermentative processes are based on a very insecure foundation.

News of the Week.

Antivivisection Bill.—The Davis-Lee bill designed to restrict vivisection, has been reported by the Senate Judiciary Committee, and its advocates are making strenuous efforts to secure its passage at this session of the legislature. If it should receive legislative approval and become a law the progress of medicine would be seriously hampered in this State, and it is highly desirable that a vigorous protest against it be made by all the physicians of the State. The chairman of the Committee on Legislation of the State Medical Society is Dr. Frank Van Fleet, 64 Madison avenue, New York City.

International Sleeping Sickness Conference.—The second International Sleeping Sickness Conference has terminated without being able to agree on the draft convention before it. The French and Italian plenipotentiaries declared themselves unable to accept a proposal, made at the last conference in June and then unanimously recommended, for the establishment of a central bureau in London, and they proposed that the work connected with sleeping sickness should be taken over by the hygienic bureau, which a conference held in Rome in November last as a sequel to the Paris conference of 1903 has proposed should be established in Paris. This proposal the German plenipotentiaries declined to accept, and they strongly support the British plan for the establishment of a bureau in London. The French plenipotentiaries were also unable to agree to other parts of the draft convention, and, although the majority of the powers represented supported these proposals, it was found useless to proceed further in the absence of unanimity.—*Science.*

Plague in Venezuela.—The State Department is reported as having received from the American Consul at La Guayra a despatch stating that a disease whose nature has not yet been disclosed by the health authorities but which is supposed to be plague, is causing many deaths in that city. The port has been closed to commerce by the Venezuelan Government.

Smallpox in Philadelphia.—The discovery that a negro couple from Wakefield, Va., who had come to Philadelphia on their wedding trip, were suffering from smallpox, recently led to the vaccination of some 1,500 persons living in the vicinity of the dwelling in which the visitors had been received as guests.

For Sanitation in Havana.—The Havana City Council has approved a plan for the paving of the city streets and the improvement of the sewerage system at a cost of $15,000,000.

Accidents on the Street Railways.—During the month of March forty-four persons were killed in the street traction lines of this city. During the month of February the number was eighteen.

Bequests to Hospitals.—By the will of the late Clemence L. Stevens the following institutions receive bequests: The Home for Incurables, the American Female Guardian Society and the Five Points House of Industry, $10,000 each; the New York Circulating Library for the Blind, $5,000; St. Thomas's Protestant Episcopal Church, for a free bed in St. Luke's Hospital, $5,000; the New York Home for Convalescents, $2,000; St. Luke's Home for indigent Females, $3,000; the Home for Old Men and Aged Cripples, $1,000; the Society for the Relief of the Destitute Blind, $2,000; Manhattan Eye and Ear Infirmary, $1,000; St. Luke's Hospital, $2,000; Home of Rest for Consumptives, $2,000; Presbyterian Hospital, $2,000; Peabody Home for Aged Women, $2,000. Under the will of the late Samuel Scholle, bequests of $1,000 each are made to the Mount Sinai Hospital, the Hebrew Benevolent and Orphan Society, the Montefiore Home for Chronic Invalids, and the Home for Aged and Infirm Hebrews. The Northeastern Dispensary is left $250.

Large Bequest to St. Luke's Hospital.—By the will of the late William Wheeler Smith the major part of his estate, estimated as amounting to between $2,000,000 and $3,000,000, is to go to St. Luke's Hospital on the death of the testator's widow, and during her lifetime a considerable portion of the income from this amount is to be paid to the hospital. Mr. Smith was an architect, and the College of Physicians and Surgeons, the Sloane Maternity Hospital, and the Collegiate Dutch Church are among the buildings he designed.

Bequests to Philadelphia Institutions.—By the will of the late Mrs. Jane B. Shain, a former Philadelphian, who died recently at Atlantic City, the sum of $1,000 is bequeathed to the Atlantic City Hospital, $1,000 to the Mercer Memorial Home for Women, and $1,000 to the Children's Seashore House.

State Hospital Transferred.—Bills have been prepared for the transfer of the State Hospital for the Insane at Flatbush to the Creedmoor rifle range ground at Flushing, L. I., which has been abandoned for military purposes. The present Long Island State Hospital at Flatbush is overcrowded and at Creedmoor more ample accommodations can be provided.

Chaille Memorial and Jubilee.—On May 19, 1908, the alumni of the Medical Department of Tulane University propose giving a Stanford E. Chaille Jubilee to celebrate the anniversary of the fiftieth year of teaching service of the Dean of the Medical Department, Dr. Chaille, who is about to retire at the end of the current year. It is the intention to establish a memorial fund for the endowment of a chair of physiology or hygiene to be named after Dr. Chaille. The funds derived are to be invested in a dormitory for medical students and the revenue employed for the support of the chair. The chairman of the committee organized for the purpose is Dr. A. L. Metz and the secretary and treasurer is Dr. Isadore Dyer, both of New Orleans. Checks should be made payable to the Chaille Memorial Fund, P. O. Box 778, New Orleans, La.

Seaman Prize.—The time limit for the receipt of essays in competition for the prize of $100, offered by Dr. L. L. Seaman for the best paper on "The Economic Waste Due to Occupational Diseases" has been extended to June 15. Each essay must contain not more than 5,000 words and be signed by a *nom de plume*, the real name and address being enclosed in a separate sealed envelope. Competitors should address Mr. Josiah Strong, President American Institute of Social Service, 231-241 West Thirty-ninth street, New York City.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission will hold examinations on May 9, 1908, for the following positions: Health Officer, Town of Brasher, St. Lawrence County; Physician, State Hospitals and Institutions, salary, $900 and maintenance. The last day for filing applications for these positions is May 2. Full information and application forms may be obtained by addressing Mr. Charles S. Fowler, Chief Examiner of the Commission, at Albany.

The Southern Medical Journal.—A new journal with this title is to be published in Nashville, Tenn., under the editorship of Dr. J. A. Witherspoon, with Dr. W. A. Bryan and Dr. J. M. King as managing editors. The editorial staff and the list of collaborators are large and comprise many of the leading southern physicians. The first number, to appear on June 5, will contain a tribute to the late Dr. Richard Douglas.

Examination Expert Arrested.—At the instance of the State Board of Regents a young man was arrested last week as the result of advertising his willingness to substitute for less gifted individuals in the State examination and secure for them medical or legal certificates for $1,000 each.

Fairfield County (Conn.) Medical Society.—At the one hundred and sixteenth annual meeting of this society held in Bridgeport last week the following officers were elected: *President*, Dr. D. C. Brown of Danbury; *Vice-President*, Dr. Samuel Pierson of Stamford; *Secretary*, Dr. F. W. Stevens of Bridgeport; *Treasurer*, Dr. J. D. Gold of Bridgeport.

New Hampshire Medical Society.—The one hundred and seventeenth annual meeting of this society will be held in Concord, May 14 and 15, 1908, under the presidency of Dr. John H. Neal of Portsmouth. The secretary is Dr. D. E. Sullivan of Concord.

McGill Medical Society.—At the annual meeting of this society held in Montreal on April 9, the election of officers resulted as follows: *Honorary President*, Dr. Blackader; *President*, Mr. Watson A. Lawrence; *Vice-President*, Mr. L. M. Lindsay; *Secretary*, Mr. W. G. Hepburn; *Assistant Secretary*, Mr. W. R. Stone; *Treasurer*, Mr. H. B. Hovey.

Nashville Academy of Medicine.—The annual banquet of this organization and the Davidson County Medical Society was held in Nashville on April 7. The following officers were elected to serve for the ensuing year: *President*, Dr. W. H. Witt; *Vice-President*, Dr. Wm. Litterer; *Secretary*, Dr. Holland E. Tigert.

Brockton (Mass.) Medical Society.—The following officers were elected at the meeting of this organization held on April 9: *President*, Dr. J. P. Shaw; *Vice-President*, Dr. W. P. Safford; *Secretary*, Dr. R. A. Elliott; *Treasurer*, Dr. E. E. Goodwin.

Association of American Teachers of the Diseases of Children.—The Association of American Teachers of the Diseases of Children will hold its annual meeting in Chicago on June 1. The membership of the organization is made up of those actively engaged in teaching pediatrics or holding positions in pediatric clinics or hospitals. All such are invited to join the Association; and all physicians and surgeons interested in children are invited to attend the meeting. Its objects are the study of the teaching and practice of pediatrics. The officers of the Association are as follows: *President*, Dr. Samuel W. Kelley; *Vice-President*, Dr. Chas. Douglas; *Secretary*, Dr. Robert A. Black of Chicago; *Treasurer*, Dr. George G. Cattermole.

Obituary Notes.—Dr. I. W. Bothwell of Wellborn, Fla., died on April 4 after an illness of two months. He was a graduate of the University of Georgia and had practised in Wellborn since 1884.

Dr. George E. Thompson of Boston died on April 12 at the age of fifty-nine years. He was born in Durham, N. H., and was graduated from Dartmouth College in the class of 1879, receiving his medical degree from Harvard medical school five years later. He had been connected with several of the Boston Hospitals.

Dr. William J. Ford of Washington, Conn., died on April 1 after a brief illness. He was born in Washington, and received his medical degree from the College of Physicians and Surgeons of this city. He held several public offices, and at one time represented Washington in the General Assembly.

Dr. J. Alexander Wade of Danbury, Conn., died on April 11 after a long illness at the age of forty-nine years. He was born in Ulster County, N. Y., and was graduated from Bellevue Hospital Medical College about fifteen years ago, since which time he had practised in Danbury.

Dr. Ralph Wilder of Medfield, Mass., died sud-

denly on April 17 at the age of thirty years. He was a native of Winchendon and was a graduate of the Dartmouth College Medical School.

Dr. Dewitt Crumb of South Otselic, Chenango County, N. Y., died last week at an advanced age. He was a Civil War veteran.

Dr. John Wilson Robie of this city died on April 15 at the age of seventy-one years. He was a graduate of the College of Physicians and Surgeons.

Dr. James King Crook of this city died after a short illness on April 16 at the age of forty-nine years. He was a graduate of the New York University Medical School, and had been connected with a number of hospitals and dispensaries.

Dr. William M. Coke of Portland, Ore., died on April 1 at the age of eighty-two years. He was born in Canton, O., and was graduated from Jefferson Medical College in 1850. He served as surgeon through the Civil War, and settled in Portland in 1889.

Dr. Geo. C. Richards of Glastonbury, Conn., died on April 10 at the age of eighty-seven years at the home of his son, Dr. H. G. Richards. He had practised in Danbury for over thirty years and about six years ago retired to Glastonbury.

Dr. Charles H. Hubbard of Essex, Conn., died on April 12 at the age of seventy-one years. He was born in Bloomfield and had practised in Essex for forty-eight years.

Dr. Mary A. O. Hunt of Manchester, N. H., died on March 25 at the age of eighty-eight years. She was born at Gilmanton and after graduating from the New England Female Medical in 1863 began to practise in Manchester.

Dr. Catherine M. Kennedy of Springfield, Mass., died on April 10 at the age of sixty-four years. She was born in Ireland and was graduated from the Woman's Medical School of the University of Pennsylvania in 1873. Since that time she had practised in Springfield.

Dr. S. H. Clisbe of Coldwater, Mich., died on April 7 at the age of sixty-five years. He was born in Quincy, Branch County, and was graduated from the University of Michigan in 1868. He had practised in Coldwater over thirty-five years. At one time he was president of the Tri-State Medical Association of Michigan, Ohio and Indiana.

Dr. D. B. Allen of Wichita, Kan., died on March 30 in Kansas City at the age of seventy-two years. He was born in Oberlin, O., and had practised in Wichita since 1869. He was the first mayor of the city, had served in the legislature, and held other public positions.

THE HARVEY SOCIETY LECTURE.

The ninth of the present series of lectures given under the auspices of the Harvey Society was delivered on Saturday evening, April 18, by Professor A. E. Taylor, of the University of California, the subject being "The Rôle of Reversed Ferment Reactions in Metabolism."

After a few introductory remarks, the speaker said that three main points should be considered: 1, What was the status of the reversion theory; 2, What were the specific facts showing that the theory holds; and 3, What still obscure facts in physiology were readily brought in line with the theory. Before discussing the first point, Professor Taylor described what was meant by enzyme action, and said that there still appeared to be considerable misunderstanding concerning this subject. He pointed out that the actions in question could be grouped under three heads: namely, anhydrations and hydrolyses, reductions and oxidations, and reconstructions. So far as the last-mentioned was concerned, there could be reconstructions with alterations of the molecular mass, and without such alterations. It was important to remember, the speaker said, that in enzyme actions there was no energy relation involved. Enzymes merely accelerated the velocity of already existing reactions. Some misguided writers had said that enzymes violated the law of the conservation of energy, and that was pure nonsense. It was impossible for enzymes to originate a chemical reaction. All modern chemistry was based on the conception of a reversion of chemical reactions. Nernst had expressed the view that all chemical reactions were reversible, and this was probably true. It had been said that colloidal reactions were not reversible, but really so little was yet known about colloids that this might be disregarded. Certainly the experimental data concerning colloid reactions were very conflicting. The speaker believed that colloidal reactions were probably made up of purely chemical reactions plus capillarity.

Professor Taylor then discussed the laboratory synthesis of various groups of substances and took up first the sugars. The synthesis of a monosaccharid had not yet been accomplished, and the difficulties were considerable. Nernst had calculated that a pressure of thirty atmospheres would be necessary to synthetize lactic acid. The synthesis of the fats, on the other hand, was quite readily accomplished, and several instances were given. Synthesis of the proteins was difficult. Emil Fischer had pointed out how important it was to have all the various factors involved properly adjusted. The least oversight was fatal to success.

The speaker then took up the synthesis of proteins in the living organism, and showed how the original oxygen and nitrogen were combined to form nitrous and nitric oxide. There was an equilibrium between these two oxides. In this connection, he spoke especially of the important biological rôle played by bacteria in building up these nitrogenous compounds. The next step in the synthesis was the formation of amides and ammonia, and after this the addition of fatty acids produced amidoacids. Many of the lower forms of life could carry out this process entirely, but the higher forms needed to be supplied with the fatty acids. The next step after the addition of the fatty acids was the introduction of sulphur and the benzol ring. In this way there were produced thioamido acids and benzol amido acids, and these could then be built up into protein. The animal organism was unable to supply the sulphur and the benzol ring; these had to be synthetized in the vegetable kingdom. The speaker pointed out that lower plants could complete the entire cycle of the synthesis as just outlined; in man only a small part was carried out. He also stated that all of the reactions mentioned above were reversible in the organism in which they occurred.

In the portal vein of an animal we find ordinary protein, not special protein such as was ingested. Where did this come from? The only explanation was the assumption of a condensation of cleavage products, that is to say, a synthesis due to reversed ferment action in the intestinal wall. In this condensation there was an intramolecular rearrangement of the amido groups. In fact the specialized proteins should be regarded as substances in which the amido groups were peculiarly arranged, or in

which there might be certain special amido groups or even none at all. The last was the case with gelatin, and this fact explained why gelatin could not be made to sustain life.

Professor Taylor passed on to the metabolism of carbohydrates, and discussed the rôle of reversed reactions. A great deal of the work in this special field had been done by Walter Loeb. In the synthesis of carbohydrates there were formed from the carbon dioxide and water, formic acid and formaldehyde. By introducing an amido group and amido acids, the former was built up into protein; and it could readily be seen how the formic acid could also be built up into fats by the addition of fatty acids and glycerine. In synthetizing the various carbohydrates it was difficult to know whether the process was always one step at a time, whether it was from one sugar to the next higher. It was probably not the case. The speaker discussed the formation of sugars in various plants, at various periods of their development, and showed how cane sugar originated from a synthesis of dextro and lævo glucose. In the animal body the only sugar found in the blood was dextro glucose. It mattered not what the sugar ingested had been. Hence there had been some rearrangement of the molecule in the body. It was probable that the animal body always first converted the ingested sugars into glucose and so burned them. There was some evidence to show that the glucose was really utilized through a stage of ethyl alcohol. The speaker demonstrated a scheme showing how glucose might be broken down in this way.

Professor Taylor then took up the metabolism of fats. The body fat of an animal varied according to the source of the fat. When it had been synthetized from carbohydrate and other food ingested, it was found that the body fat was specific to the animal species in which it was formed. But when the body fat was derived from ingested fat, it was similar to the fat of the diet. The combustion of fat in the body was not well understood. It was improbable that fat was burned in plants. In plants, the entire series of reactions was reversible; in animals only a small part was so.

Purin metabolism was next discussed. Fully developed animals were apparently unable to utilize the purin group compounds. Curiously, this was not true for growing embryos. The speaker said he knew of but one instance of a reversion of reaction in purin group compounds in animal life, and that was in the case of some fish eggs. But even here the amount of such substances utilized was not large.

In discussing the mechanism by which reversion of reaction is accomplished the speaker said that this was still very obscure. The ferment had nothing to do with the direction of the reaction. All it could do was to accelerate the reaction, and this occurred entirely irrespective of the direction which the reaction chanced to have at that particular moment. In chemical reactions outside the body, thermic and photochemical influences could cause a reversion of the reaction, but these did not enter into consideration in animal metabolism. He would have to admit that he was entirely at a loss for an explanation. In ordinary chemical reactions the quantity of the catalyzer was of no consequence, but in the animal body this had been found not to be true. But even these differences in the quantity of a ferment at a given time could not explain reversion.

In closing, the speaker alluded to the unfortunate influence, in his opinion, which Ehrlich's views of multiple, specific antibodies had had on the development of this subject. It had been assumed that every ferment action had its own special ferment, and the idea was not grasped that ferments could accomplish various different actions, and in both directions.

At the close of the lecture, Dr. Flexner moved the thanks of the Harvey Society to Dr. Taylor for his résumé of physical chemistry as applied to biological problems. The next and last lecture of this series will be delivered on May 9, by Professor E. A. Schäfer, of the University of Edinburgh, who will speak on "Artificial Respiration in Man."

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

UNITED KINGDOM HOSPITALS' CONFERENCE—FRACTURES OF LONG BONES—ENTOZOA—FILARIA—OBITUARY.

LONDON, April 3, 1908.

YESTERDAY the third United Kingdom Hospitals' Conference concluded its deliberations. It was opened on Wednesday and has been attended by representatives of many hospitals, both of the medical staffs and subscribers. On the first day the abuse of hospitals and payments by patients were the chief questions discussed. Mr. Gosnell, of the City Lying-In Hospital, holding that hospitals did not exist solely for the working classes, said that men who bore no obvious signs of poverty were often deserving of the benefits of charity because their obligations exceeded their means. He proposed a resolution to the effect that such persons should be deemed eligible if, owing to that disproportion between means and obligations, they could not pay for medical assistance. Mr. Dodson, of the Brighton Women's Hospital, seconded the resolution, but, after discussion, it was lost. Mr. Johnson (Leicester Infirmary) thereupon moved that "it is desirable to supply gratuitous hospital relief to those who are provided for by the Workmen's Compensation Act." He said the compensation could not exceed £1 per week, and he thought it would not be right to make them pay. Dr. Fowler of Bournemouth proposed to add to this resolution, "whom the Hospital Board shall consider unable to pay," and with this addition the motion was adopted.

As to payment by patients, the Hon. Sydney Holland (London Hospital) moved that when they can do so, patients "ought to be asked to pay for the food, medicines and bandages supplied." He said it was economically unsound to give everything to everybody. Last year, without any pressure, 157,000 persons contributed £2,000 to the coffers of the London Hospital. Charitable work should be restricted to those too poor to provide for themselves. Many breadwinners, such as policemen, postmen and clerks, received their usual wages during illness, but gave nothing to hospitals. When the workman understood the matter he would be willing to contribute. Mr. W. Carnt (Manchester Infirmary) said in his institution the inmates paid from 2 shillings and 6 pence to 7 shillings and 6 pence a week, and so added £1,100 to £1,200 a year to the funds. The Rev. W. Blissard thought the proposal would tend to increase the range of applicants and so injure the medical profession, and Mr. Capes said the result would be a great increase of cheap dispensaries around the hospitals. The proposal was pronounced wrong in principle by others, including Dr. Davey, president B. M. A., who preferred the German system, and Dr. Beverley, who thought Mr. Holland was trying to begin at the wrong end. Dr. Heron held that the proper people for hospital treatment were the necessitous poor. He knew of persons, mostly clerks, earning from £250 to £800 a year who went to hospitals. Mr. Holland, in reply, said the necessitous poor were provided for in the poor law infirmaries, and it was struggling men on a small income who most needed charity in illness. On a show of hands the motion was carried.

Lieutenant-Colonel Montefiore proposed a resolution in favor of appointing trained almoners, on which Sir B. Fuller (Royal Hants Infirmary) remarked that such a step would be of little use until they had settled what classes should benefit from hospital treatment. Mr.

Jewson (Norwich Hospital) said the employment of almoners had greatly mitigated the abuse of the out-patient department there. This motion was carried, and Mr. Harben (treasurer of St. Mary's Hospital) proposed that abuse of out-patient departments can be most effectually prevented by cooperation with provident dispensaries and local practitioners. He quoted statistics showing that in London the abuse had increased out of all proportion to the increase of pauperism. Close cooperation with provident dispensaries for preferential treatment of patients recommended by them was urgently needed. The resolution was carried, and the conference adjourned.

On resuming work yesterday a resolution was carried in favor of taking definite steps to ascertain the ability of every patient of a cottage hospital to pay for his maintenance.

The committee was then instructed to consider how the uniform system of accounts recommended by the King's Fund could be applied in provincial hospitals and to make recommendations to the next conference. the organization of the county guilds for the support of hospitals was the next subject. On this most interesting information was given by Mr. Kinsey and Lord Ampthill of the Bedford County Hospital Guild. Not that this work is altogether novel, but it is a plan of coordinating existing efforts so as to prevent overlapping and to secure an equal distribution over the whole area of all philanthropic work, a concentration of control and decentralization of management, giving smaller organizations the additional strength of their united efforts.

The Bedford guild was formed to secure in every town and village in the country a representative of the hospital, who would be constantly urging its claims on his or her neighbors and gather in a large number of small subscriptions, and these representatives, having local knowledge, would take care that abuses did not occur.

Dr. Fox, of the Plymouth Eye Infirmary, then suggested that the King's attention might be called to the provincial hospitals, and his sanction sought for establishing a King's Fund on their behalf.

The next question was the notification of tuberculosis. This the Rev. W. Blissard (Canterbury Hospital) strongly urged, with a view to the isolation of such patients in publicly provided hospitals. He recognized that the expense of such provision would be enormous.

Dr. Henry Davy, president of the B. M. A., moved an amendment in favor of asking the government to appoint a royal commission to recommend the best way of dealing with tuberculosis. He thought there might be a difficulty in getting a commission, considering Dr. Bulstrode's recent report (of which I gave you some account). But notification alone, he said, would be of no use, and there was needed some uniform system of treatment to be adopted by all the sanitary authorities of the kingdom. A body of influential men, medical and lay, could best consider the question, and they could only be brought together by a royal commission. This amendment was seconded by Dr. G. A. Heron (City Hospital for Chest Diseases), accepted by Dr. Blissard and unanimously carried.

A paper was read by Dr. Ford Anderson in favor of medical men nominating representatives to committees of hospitals in their localities, and he suggested that the British Medical Association should organize such nominations, a project which excited no little opposition and was lost by a great majority.

Dr. Griffith (Leeds) submitted a motion to provide temporary accommodation in hospitals for certain cases which could not be certified as lunatics, but over which it was most desirable to keep control for a time for the purpose of observation. This was carried and the conference came to an end with the appointment of a new committee and the usual votes of thanks.

Radiography in relation to the diagnosis of fractures and other injuries has taken a large place in the estimation of the public in consequence of proceedings in the law courts. In the profession, too, the assistance of the *x*-rays has been fully appreciated. So much so, in fact, that many seem inclined to underrate the value of other methods. Yet it must be admitted that an accurate radiogram is by no means easy to secure. Moreover, the most careful observer may not always correctly interpret the appearances. A recent discussion at the Medical Society of London gave rise to considerable differences of opinion among our leading surgeons as to the "diagnosis and treatment of fractures of the long bones," and, incidentally, as to the points mentioned above.

It was opened by Mr. A. Pearce Gould, than whom no one is more capable of directing surgical opinion. He said the classical signs of fracture, suddenly produced deformity, localized pain, and tenderness, and oftentimes mobility, with crepitus, were sufficient to lead to the recognition of the majority of fractures, and he added that the introduction of *x*-rays and other means ought not to lessen the thoroughness of the older methods of investigation. Anesthesia he found of great use. The *x*-rays could sometimes demonstrate a fracture when other means had failed, or only given rise to strong suspicion. So it might be possible in some cases to take the position that recognition of the fracture was not of great importance in regard to prognosis, for instance, fractures of the carpal bones, incomplete fissures of the scapula or long bones, and simple fissured fractures of the vault of the skull. Then serious displacement might be concealed by swelling, and other circumstances might obscure the skiagram, such as a very indistinct line of fracture and want of care in taking it might so distort the shadow as to give the appearance of a displacement. The normal epiphysial junctions might easily be mistaken for fractures. As to treatment, he advised anesthetics to assist reduction, immediate whenever possible, and held that splints must never be used to help this last, only to maintain the fragments in the correct position. The chief debatable point was the necessity for exact and perfect adjustment of fragments. Could restoration of function be expected unless replacement was so exact as to cause no interruption in the mechanical adaptation of the bone to its purpose? Experience has shown that even considerable alterations in the shape of a bone might under some circumstances not be very harmful. Examples: Fracture of the clavicle and Colles' fracture. In the weight-bearing bones of the lower limbs serious deformity was attended with functional imperfection. As to operative treatment of simple fractures, he said the operations were not very easy, were rather more risky than most modern surgical operations; in some cases the mechanical difficulties were very great, and the use of screws, wires, staples, and plates—though of undoubted value—was attended with disadvantage, for they added to the local injury and lessened the rapidity of repair. When employed, the procedure should be of the simplest, provided it was efficient. A wire ligature round the fragments would often hold them in place; if so, it should be preferred to anything introduced into the bone. Massage was often useful, and active movements better than passive. In fractures near or even into joints, patient, gentle manipulations and use of the part would do good when violent or rough handling did harm. There was evidence of a power of compensation for deformity, as some patients who were at first lame after a time lost their lameness. It would be of value to discover how far this compensation for deformity could go.

At the meeting of the Society of Tropical Medicine and Hygiene, Mr. A. E. Shipley read a paper on the relation of entozoa to the mucous lining of the alimentary canal, in which he traced the various entozoal infections of the lower animals and man and showed the consequences that might occur from the presence of the parasites. He described the parasites that infest the intestines of grouse, of fowls, and of the horse, and reviewed our knowledge of the entozoa in man. He suggested that possibly appendicitis might be caused by *Trichocephalus trichiurus*. This suggestion received no support; indeed, it was repudiated by all the subsequent speakers. Dr. Daniels cited against it the fact that though the natives of the tropics were much infested by that parasite they very rarely suffered from appendicitis. On this, however, Sir Havelock Charles remarked that he found appendicitis was not uncommon in Lower Bengal. Sir Patrick Manson said statistics fully supported the general belief that there was no definite connection between the parasite and the disease.

A paper was then read by Dr. W. T. Prout on the rôle of filaria in the production of disease. The adult *Filaria loa* was a worm, the habitat of which was the connective tissue, and when it came near the surface in a part where the tissues were thin and lax it became visible. The embryonic form seemed to be a microfilaria, which showed a degree of diurnal periodicity. He thought recorded cases justified him in associating *Filaria loa* with calabar swellings, but he attributed the local phenomena to the irritation of the adult worm forcing its way through the connective tissue near the surface. *Filaria nocturna* was associated with a long list of diseases connected with inflammation and obstruction of some part of the lymphatic system. But he did not think the invariable connection of *Filaria nocturna* with

elephantiasis had been fully proved, for the production of the disease experimentally and recognition of the parasite afterwards had not been shown. He described a case where obstruction in a main trunk set up elephantiasis, but was inclined to hold that most cases were of peripheral origin, due to a lymphangitis caused by the introduction of a specific microorganism, resulting in the gradual narrowing and obstruction of the peripheral lymph vessels. He suggested that during elephantoid fever an attempt should be made to examine the serum, and he anticipated that some skilled observer would demonstrate some specific organism. Discussion of this paper was deferred to another meeting.

Dr. James Bell, C.B., F.R.S., late Principal of the Laboratory of the Inland Revenue Department and Consulting Chemist to the Indian Government, etc., died on Tuesday after a short illness, in his eighty-fourth year. He received the D.Sc. of Dublin, 1886, was President of the Institute of Chemistry, 1888 to 1891, and in 1889 was made a C.B. He made many important researches on food, which are embodied in his work on "The Chemistry of Foods," which is the handbook at the Kensington Museum, and has been translated into German. Many other contributions to chemical science were also made by him. He retired in 1894.

OUR CANADIAN LETTER.

(From Our Own Correspondent.)

THE HOSPITALS OF ONTARIO—ASSOCIATION FOR PREVENTION OF TUBERCULOSIS—TORONTO ACADEMY OF MEDICINE—DOMINION BUREAU OF HEALTH—MEDICAL EVIDENCE IN A CANADIAN COURT—COMING MEETINGS OF MEDICAL ASSOCIATIONS.

TORONTO, March 31, 1908.

THE annual report of the Inspectors of Hospitals for Ontario has just been issued and is full of interesting information. There are sixty-five public hospitals which received aid from the government, to the amount of $145,900. The total expenditure for the support and maintenance of the hospitals of Ontario for the past year was $1,415,140. The number of patients admitted during the year was 45,551. The provincial government grant is paid to hospitals during the first ten years of their existence at the rate of 20 cents per day for each patient. After a hospital has been in existence for ten years the grant is paid only for patients for whose maintenance $4.90 per week or less is contributed. In all cases the limit of hospital residence is 120 days, and if patients remain in the hospital longer than that period the rate is reduced to 7 cents per day. Each hospital in Ontario is regularly visited by the inspector, and all rules and regulations adopted by local boards for the government of these institutions have to be submitted and approved of by the government before they become operative. In this way the whole hospital system of the Province of Ontario is under government control and regulation. After each visit of inspection a report is presented to the government and a copy of the report sent to the hospital visited. This inspection report covers all matters relating to the conduct of the institution and describes the conditions found prevailing. It is now a well-recognized fact that a well-conducted hospital confers incalculable benefit on the community in which it exists. The remarkable progress that has been made in Ontario during recent years in establishing public hospitals has developed an appreciation of the material advantage that such an institution is to the city or town in which it is located. It is only a few years since, to secure proper hospital accommodation, a long railway journey was necessary. Soon every county in Ontario will have its own hospital, properly equipped for the care and treatment of medical and surgical cases. To-day the equipment of many of the smaller hospitals is superior to that found in some of the old-established institutions in the larger cities. The effect in every county where a public hospital has been established is seen not only in affording proper care for the sick, but also in fostering and developing an appreciation of scientific advantages to the medical profession that ultimately are of the greatest benefit to the whole community. The Province of Ontario has evidently come to realize that from the standpoint of value to the country, hospitals rank first in the list of deserving philanthropies. The system of government inspection has certainly not only raised the standard of the hospitals, but has stimulated a great public interest, as shown in largely increased contributions and bequests.

The Canadian Association for the Prevention of Consumption and Other Forms of Tuberculosis met in annual session at Ottawa last week. Representatives were present from every province, from the Atlantic to the Pacific. The reports presented indicated that in every province an organized effort is being made to educate the public in regard to the nature of the disease and the means that may readily be adopted to prevent its spread. For example, it was reported that in the city of Montreal the Health Committee has taken over the duty of disinfecting the houses in which tuberculosis patients have died. The inspector of the local society in Montreal has, during the past two months, made 814 visits, and distributed 5,000 paper cuspidors and 7,000 pamphlets. Two hundred and thirty new cases were reported during the past quarter to the Montreal society. Provision is made for distributing milk, eggs, and other food and also to carry out an organized system of district nursing. From the Province of Ontario the reports presented indicated that a system of notification is about to be enforced by law, so that the provincial Board of Health will be notified by the local boards of every case of tuberculosis. Plans are now being carried out to furnish every householder with plain, easily understood directions for preventing the spread of the disease. In addition, the government of Ontario has provided an elaborate exhibit, which will be taken to every city and large town in the province, and old and young be given demonstrations that cannot fail to prove of the greatest benefit, and all for the purpose of teaching people how to live in order to eradicate tuberculosis. All the provinces of Canada are taking a lively interest in the question, and a large Canadian delegation will, no doubt, be sent to the International Congress on Tuberculosis at Washington in September.

The Academy of Medicine at Toronto is now well organized, and already a good deal has been done to justify its existence and prove its success. There are four sections, meeting regularly, the last one to be formed being one in State Medicines. The constitution and bylaws providing for the formation of the new section having been complied with, a meeting for organization was held and officers elected. There is an excellent field for such a section. The water problem in Toronto, the milk supply, the smoke nuisance, the vaccination question, the cleaning and ventilation of railway carriages, and the medical inspection of schools are likely to be carefully and profitably discussed by this new and live section of the academy.

A deputation of medical men, many of whom are Members of Parliament, waited upon Sir Wilfrid Laurier this week and urged that legislation should be introduced in the House of Commons during the present session to constitute a Dominion Bureau of Health for Canada. The Canadian Medical Association has repeatedly asked for such legislation. While all acknowledge that the provincial Boards of Health are each doing excellent work, it is generally recognized that there is a wider field for usefulness for a central board, without any danger of encroaching on ground already occupied. For example, a Dominion Health Bureau might protect the public against impure and adulterated food by extending its operations to the work of the Inland Revenue Department. The value of the educational work that might be done through a Dominion Bureau publishing information for the people in regard to prevention can scarcely be estimated. The deputation which waited on the Premier this week pointed out to him that 8,000 people die in Canada each year from tuberculosis. These died at an average age of 22 years. The value of each life to the community would be $8,800, and for 8,000 lives the sum would be $70,400,000. To this large amount must be added the value of the vast number of lives which are every year lost by deaths from diseases of a preventable character. The indications seem at present very favorable for the establishment of a Dominion Bureau of Health at an early date.

An instance of the manner in which Canadian justice is dispensed is commented on by the press this week. A man charged with the murder of his wife under the most revolting circumstances, was arraigned for trial at London Assizes, before his Lordship, Mr. Justice Riddell. When called upon to plead, counsel for the prisoner insisted that, on account of insanity, the prisoner was incapable of pleading. Three experts in insanity had previously made careful examinations on behalf of the Crown. These witnesses were called and testified that the prisoner was a dement, and on that account could not appreciate the position he was in when called upon to plead. In less than forty minutes from the commencement of the trial the verdict was returned by the jury that the prisoner was insane and, therefore,

incapable of conducting a defense or instructing his counsel. A defense of insanity is not very frequently resorted to in Canadian courts, but when the Crown has to meet such a defense, every facility is provided for a thorough and careful examination to be made. Everything is done to prevent a parade of conflicting medical testimony in open court, and medical men generally discourage the ventilation of different opinions in a court of law. The present method of having consultations before the trial and insisting on a conclusion being reached is fair, just, and seemly.

The meetings of the Ontario Medical Association at Hamilton, May 26-28, and the Canadian Medical Association at Ottawa, June 23-26, promise to be largely attended. For the provincial meeting at Hamilton an unusual effort is being made, and the attendance is likely to be one of the largest in the history of the association. The meetings are generally held at Toronto, but for this year a change was made in order that the medical men of Hamilton might have an opportunity of bestowing the hospitalities which have always made the Toronto meetings so pleasingly attractive. The meeting places of the Canadian Medical Association are changed each year. This year at the capital there will, no doubt, be a large attendance, and an interesting program is being prepared. Canada is also to be favored this year with the American Hospital Association, which is to meet at Toronto during the last week in September.

LODGE PRACTICE.

To the Editor of the Medical Record:

Sir: The paper by Dr. J. Weiss on the society and lodge practice in the east side of New York City, has brought back to my mind some reminiscences of attempts on my part to derive my livelihood by practising my profession in that district. Although my experiences in this direction date back only a few years, still I have nearly forgotten all about them. It is a well-known fact in psychology that pain is more easily forgotten than pleasure. I am under the impression that Dr. Weiss has not said everything that can and should be said about the contract practice in vogue in that part of the city, and I believe that a few additions to his paper may prove interesting to many of your readers to whom the east side of New York is an unknown region.

Superficial observation would lead one to believe that the lodge practice cannot be remunerative to the physician. No actuary would approve of such a contract as is generally made between the physician and the lodge. It practically provides that, in consideration of the services rendered to the members of the society by the physician, the treasurer of the lodge will pay to the latter one dollar per annum for each unmarried member, and three dollars—often only two dollars—per annum for each married member who consents to place his name on the doctor's list. Inasmuch as the enrollment on the doctor's list is not obligatory for every member, it usually turns out that very few of the single members, or childless couples, enroll. Most of those the doctor finds on his list have several children who rather too often need medical attendance. It thus appears that the doctor is always at a disadvantage from a financial standpoint.

Curious as it may appear at first sight, still it is a fact that many physicians whose chief support is derived from lodge practice have incomes which compare favorably with the income of a successful practitioner in a well-to-do neighborhood. Moreover, I know several lodge doctors who make annually about six times as much as the average privat docent in Germany or Austria, and yet do not work much harder than he. How is that done? Very simple. Twenty societies averaging fifty members on the doctor's list gives an assured income of about $2,500 annually; three hundred confinement cases annually, averaging twelve dollars each, $3,600; then injections of antitoxin, which, while not overdone, still very often employed in that neighborhood, will bring to such a physician another $500; while curettements of the uterus, which are very much in vogue among the women in that neighborhood (a woman who has not been "scraped," as they call it, is as rare down there as one without a gold-filled tooth), will bring another $500; then legitimate treatment of miscarriages, which are by no means as rare as among those who are better initiated in the mysteries of "race suicide," bring another $500. To all this must be added incomes from minor surgical cases, and from the treatment of venereal (called there "immoral") diseases, and also from consultations with "professors," which have to be paid for extra, and also "private" patients, which are often recommended by the grateful lodge patients, bring no mean sum. It is no surprise, then, that there are several lodge doctors each of whom has an income of over $10,000 annually.

The vast majority of lodge doctors are not so fortunate, and are struggling very hard to pay the high, almost extortionate rents which are exacted for "parlor floors" in that neighborhood. The essentials which assure success to the lodge doctor are about the same as those of the general practitioner in fashionable neighborhoods, plus an enormous amount of altruism, self-negation, and extraordinary confidence in your fellow man. A lodge doctor, when a patient asks him this question, "Doctor, am I really dangerously ill, so that I must consult a real doctor?" must not feel offended. On the contrary, he must in trivial cases suggest a consultation with a "professor" and receive a two-dollar fee for meeting the famous professor at the bedside. I doubt whether this alone is responsible for the large number of calls consultants have in the east side. I believe that the extraordinary anxiety of the people is also responsible for it, to a large extent. The lodge doctor, knowing the weakness of human nature, must suggest antitoxin as a prophylactic in most cases presenting some suspicious signs of diphtheria, not because this is paid for extra, but because, if it turns out a bad case, he is not blamed. "I have done my best," he can say. But I have known many successful lodge doctors in the east side who injected antitoxin, curetted women, called consultations, etc., only when reasonably indicated. It all depends on the personal equation, just as with practitioners in any other district. But when his self-negation is so intense that he can tell a mother whose sick child is asleep when he calls, that it is a pity to wake the poor child, and that he will return within a few hours, he is assured of an enormous success. But, on the other hand, many are not so altruistic. It is said about some who are very busy and cannot spare the time, and the limbs, to climb up five or six flights of stairs, that they, like the letter carrier, call from the bottom of the stairs for their patient, and when he or she appears at the top floor, the doctor asks to be shown the tongue, and promptly writes a prescription, leaving it for the patient to come down, pick it up, and follow directions.

Of course, with such a complex problem as the lodge practice presents, the profession cannot deal offhand. The remedies suggested by Dr. Weiss are hardly tenable. It is doubtful whether the successful lodge doctors will agree to share their practice with their less successful colleagues. It appears to me that education of both the laity and the lodge doctors as regards the evil of this kind of contract practice may bring better results. It must be borne in mind that the future of the lodge doctor is by no means bright. It is true that for several years, as long as youthful vigor is one of his attributes, he makes money. It is also true that, having a minimum standard of life, he also saves money. But, unless he invests his savings in some remunerative ventures, he can never work long enough to accumulate sufficient funds to keep him from starvation in his old age. Once a lodge doctor, always a lodge doctor. Patients who are used to getting his services for from one to three dollars a year will, as a rule, not consent to pay him a fee for each visit. As a matter of fact, as soon as a practitioner of this kind gives up his contract practice he is practically left without a clientele. On the other hand, there are many successful practitioners in the east side who never had lodges and societies, and they get good fees for their services. The lodge doctor never reaps the benefits which are the concomitant of age and experience of the medical man. If this is brought home to the younger members of the profession, I have no doubt that they will refrain from making contracts with lodges. If, in addition, the same young men will make it their business to explain to the members of the lodges that they are by no means the gainers in the transaction, the number of people who enroll on the doctor's lists will decline. It must be shown to the "brethren" of the lodges that a large proportion of members have no confidence in their lodge doctor, and one of the results is that consultations have to be called rather too often, and the "professor" paid a fee of ten to twenty-five dollars. An ordinary case of acute disease costs thus from ten to twenty-five dollars; not less, often more, than it should cost if they had the liberty to choose a physi-

cian in whom they have full confidence, and not the one in whom the "politicians" of the organization have, for a consideration, confidence. Inasmuch as the majority of the physicians in the east side are members of lodges and benefit societies, they have ample opportunities to carry on such an agitation, which will undoubtedly bring salutary results to both the patients and physicians. The project suggested by Dr. Weiss, cannot and will not bring any relief. It is rather full of paternalism and the trade union spirit. Medical men need no keeper; they can take care of themselves. It is, however, their sacred duty to educate the laity in regard to all medical matters. A campaign of education such as I have just suggested will at least ameliorate, if not completely cure the lodge evil.

MAURICE FISCHBERG, M.D.

23 EAST EIGHTY-EIGHTH STREET.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 9, 1908.

Infantile Pyloric Stenosis.—J. L. Morse and F. T. Murphy present a detailed report of a case of this condition occurring in a male child first seen at the seventh week after birth. A successful gastroenterostomy was done and the child lived to be eight months old. During this time his weight increased from six pounds ten ounces up to nineteen pounds. He took only breast-milk and did not vomit. In fact, he developed in every way as a healthy baby should. After a rather indefinite illness of nine days he died from what the autopsy showed to be idiopathic peritonitis. Details are given of the operation and postoperative treatment; also full autopsy records. The microscopical findings in the pylorus were surprising because of the absence of degenerative changes in the smooth muscle, either in the form of atrophy or in connective tissue overgrowth. The closed state of the pylorus was proved by the mechanical tests applied and by the rigidity and thickness of the walls, which are in striking contrast to the usual post-mortem condition of the pylorus in infants. The authors regard the case as of especial interest because it shows that in some instances at least the stenosis is not due to spasm, that medical treatment cannot be of any avail, and that the only hope for relief and life lies in surgical intervention. It also proves that an infant can live and thrive for many months, although all the food passes through the gastroenterostomy opening and none through the pylorus. It suggests that the condition of organic infantile pyloric stenosis is a permanent one, that there is no tendency toward a restoration of normal conditions, and that there is little hope of the pylorus ever resuming its functions. It is not safe to draw conclusions from these suggestions, however, as it is possible that with the lapse of time and the growth of the parts, changes may occur which will result in the restoration of normal conditions and function. These points can be decided only by the actual observation of the anatomical conditions in patients dying at longer intervals after successful operations.

Congenital Stenosis of the Pylorus.—C. W. Townsend reports one case, that of a male child seen some sixteen days after birth with symptoms suggesting pyloric obstruction. The child's apparently good condition made it seem probable that some food was digested, and passed through the intestinal canal, but careful observation showed that as much was vomited as was received, and at no time was there any evidence of food material in the stools. Results of abdominal examination were negative, and operation was postponed till the twentieth day of life. A gastroenterostomy was then done, the pylorus having been found firm and enlarged, and the entire bowel collapsed. The child bore the operation well and rallied somewhat, but the vomiting continued, and it died on the third day. Autopsy confirmed the diagnosis.

New York Medical Journal, April 11, 1908.

Cammidge Reaction in Pancreatic Diabetes.—Report of a case is given by G. A. Friedman, who has found four previous cases recorded in literature. In his own case the author was able to make a diagnosis of carcinoma of the head of the pancreas, and this was verified by the results of autopsy six weeks later. He has obtained the reaction in some other instances likely to be also affections of the pancreas, but proof could not be obtained either by autopsy or operation. A bibliography is given of the literature of the last four years.

Poisoning with Tansy.—E. J. Stout's patient was a married woman of twenty years who had taken two drams of oil of tansy to bring on menstruation, although there were no evidences of pregnancy. Half an hour after taking the drug she fell to the floor, and was found with pulse of 160, respiration 40, dilated pupils, clammy skin, more or less muscular rigidity, semistuporous, and unable to answer questions intelligently. Apomorphine was given by needle, and the tansy odor was detected in the vomitus. Under liberal stimulation and in the course of an hour the woman rallied, and was soon out of danger. For several days, however, she had stiffness and soreness in the muscles of the jaws and legs. The author refers to several similar cases on record. The powers of tansy as an abortifacient seem to be somewhat overrated. In some instances it proved fatal, but autopsy revealed the ovum undisturbed in the uterus.

Comparative Therapeutical Value of the Compounds of Iron.—R. E. Van Gieson's views are expressed in the following propositions: A careful study of iron metabolism shows that the official preparations of iron so long useful in the past will increase hemoglobin. The ferrous carbonate; the soluble oxide with sugar; the double salts with the vegetable acids; the solution of the perchloride given in combination and largely diluted with milk, are the forms most likely to produce good results. Directly conflicting views as to the value of the modern proprietary preparations exist among competent observers. In all iron medication the question of defective metabolism is important. Cases must be individualized and preparatory treatment is essential. Rest in bed, massage, milk diet, unfermented grape juice, and static electricity are valuable adjuvants preparatory to or during the administration of the iron compounds.

Surgical Treatment of Appendicitis.—J. E. Cannaday details his technical procedure in these cases which he divides into chronic, acute, and pus cases. In the first and second class of cases he believes in the unqualified removal of the appendix, first, last, and always. In the third class of cases he simply incises and drains, removing the appendix, provided the condition of the patient warrants the interference, and provided that the appendix can be secured without breaking down the wall of adhesions that has been formed between the abscess cavity and the general peritoneal cavity. On general principles he does not drain unless drainage is absolutely necessary. He believes that at times it is better to drain through a stab wound so that the operation wound may be closed in the usual manner by layer sutures. Finally, he declares that all patients with appendicitis should be operated upon irrespective of the stage of the trouble. When the case is one of general peritonitis or extensive local peritonitis a small incision should be made and a cigarette drain inserted, no more, no less. Irrigation, sponging, and mopping out, breaking up adhesions, etc., in such a case, would be murderous. Postural drainage is undoubtedly of some value in these cases. He greatly favors having the patient lie on the side in which the drain has been placed for a few hours at least immediately after the insertion of the drain. The administration of normal saline enemata to the patient who is weak or exhausted gives valuable support.

Journal of the American Medical Association, April 11, 1908.

Ocular Rotation in Paresis.—Using the term "paresis" as applied only to the ocular musculature, and distinguishing it from heterophoria, by which term he understands a functional disability due to anatomical rather than pathological conditions, F. Valk discusses the anatomical conditions of rotation and the diagnosis of paresis, and summarizes his article substantially as follows: All tests for paresis must be made with the look in complete infinity and with complete acuity of vision. We must have a standard of version for comparison of any deficiency of rotation. The straight muscles are capable of moving the eyes in any part of the field of vision and from one part to another; the obliques take no part in the rotation of the eyes in the field of vision; in other words they do not elevate or depress the visual line. A distinct line must be drawn between paresis and heterophoria, as shown by the diplopia; in the first by the diplopia with the look in infinity, and in the second by the possible diplopia with reduced vision. In the consideration and diagnosis of paresis we may exclude the condition of crossed or homonymous images and also the tipping except in a pathological condition of the obliques. The individual muscles of the eye are not endowed with two distinct functions, as they have but one nerve supply, except possibly in the action of convergence and inward rotation due to two distinct nerve centers. The points of action of the straight muscles of the eye are the insertions and sheaths of the tendons as they are placed in the orbit just behind the globe.

Interstitial Keratitis.—H. H. Martin, from answers

to letters of inquiry sent by him to thirty representative ophthalmologists in different parts of the country, finds that local measures are not considered as of great value in the treatment of interstitial keratitis, and also that the great majority of his correspondents coincided with him in the opinion that iodides given internally are useless, if not positively harmful, during the inflammatory stage. A majority indicated a preference for the inunction method in the administration of mercury. The answers to the question as to the average duration of the inflammatory stage could be divided into two classes, those who assume that interstitial keratitis is always due to congenital syphilis and treat it accordingly, and those who recognize other possible causes and therefore do not rely on specific treatment alone. It is significant, Martin remarks, that the former, as a rule, gave the average duration of the inflammatory stage in weeks, while the latter gave it in months. He thinks that the majority will agree with him that the treatment resolves itself into the treatment of congenital syphilis, with appropriate measures for relief of the most prominent local symptoms, the combating of complications arising from involvement of the uveal tract and for the more rapid and complete clearing up of corneal opacities. The most obstinate cases, he is convinced, will yield to the scientific use of mercury, together with the most careful attention to diet and hygiene. What is required, Martin holds, is the maintenance of a condition of mercurial saturation, and this can best be obtained by the use of inunctions of blue ointment which do not derange the digestion and are not painful like the hypodermic administration of the drug. He gives the inunctions on alternate days, beginning with ten grains and gradually increasing the dose up to thirty grains for children and sixty grains for adults, always endeavoring to keep the patient on the verge of ptyalism, till the progressive stage has been permanently arrested; then an intermission of ten or fifteen days is ordered. When the mercury is resumed it is with half the former initial dose and is carried up to half the former maximum. If by this time there are no signs of renewal of the inflammation, the iodide of iron is given in liberal doses, together with the continued administration of mercury. While the patient should be in a hospital, he should be allowed full outdoor liberty, with suitable protection from light. The diet should be principally milk and eggs. The tincture of chloride of iron is often useful during the active treatment. The usual methods in corneal inflammations are available for the relief of local conditions. If atropine is used it should be in stronger solution than usual, as the iris is resistant. After recovery the patient should be kept under observation for six months and should take moderate doses of mercury by the mouth, with intermissions, and liberal doses of iodide of iron, together with good nourishing diet and full outdoor liberties.

Nitrogenous Metabolism in Epilepsy.—A. J. Rosanoff, reports experiments undertaken to determine whether or not in epilepsy the excretion of ammonium salts in the urine varies in any way from that in health, and if so, whether or not the variations bear any relation to the seizures. The object was not to estimate the total amount of ammonia excreted in twenty-four hours, but to determine how the rate of excretion varies immediately before and after seizures. Seven cases of idiopathic epilepsy were selected for the investigation; samples of urine were taken at two-hour intervals and put away separately in a refrigerator, with a few crystals of thymol to prevent putrefaction. When a seizure occurred, all were thrown out, with the exception of the last one or two which were analyzed. The urine passed immediately after the attack was also thrown out, as it was largely that secreted before the seizure, but that obtained from one-half to two hours after was saved and analyzed. The total nitrogen was estimated by Kjeldahl's method. Folin's method was used for the estimation of ammonia, only modified by allowing the air current to pass through the urine for six hours instead of an hour and a half. The results obtained show that the ratio of ammonia to the total nitrogen varies much more in epileptics than in normal individuals, and that the variations bears a constant relation to the seizures. Immediately before a seizure this ratio corresponds to the normal, while immediately after an attack or series of attacks, this ratio invariably rises, often far above the normal standard. He found no exception to this in the cases studied. Folin found that in normal individuals the greatest was 1.3 per cent., while the average was less than 1 per cent. In Rosanoff's cases the variation ranged from 1.1 per cent. (only two specimens examined) to 4.7 per cent. He does not venture to offer conclusions other than that it can now be considered firmly established that nitrogenous metabolism as it occurs in epileptics presents definite and striking variations from the normal, and that these variations occur in constant connection with the seizures.

Intussusception.—W. L. Wallace is sure that, if autopsies could be obtained, intussusception would be found to be a frequent cause of death in infants and young children who die, after a few days' illness, with acute intestinal disturbances. He reports a case in which the typical symptom of pain was not prominent, but bloody vomiting was present with the other symptoms of obstruction. Invagination, he says, is of frequent occurrence and is easily produced by slight irritation of the normal intestine, the bowel above rolling into the segment below and emptying itself as in a movement of the bowels. Treves goes so far as to hold that many attacks of indigestion may be due to a temporary invagination of the bowel, in which the circular fibers below rapidly contract and reduce the intussusception before adhesions have formed. Whatever would prevent such reduction would produce a true pathological intussusception. Wallace discusses the theories of the causation of intussusception, rejecting that of local spasm and contraction and holding rather to the view that intussusception is the result of damage to the bowel by some interference with its blood supply causing bulging and threatening perforation, and that the intussusception is nature's effort to reinforce the weak spot by splinting it between healthy layers from above and below. If the invagination relieves conditions so that the blood supply can be restored, the intussusception may be reduced spontaneously, but if the damage is too great, adhesions form and reduction is impossible. Then nature will attempt to unite the neck of the intussusception to the healthy bowel below so that there will be no leak when it sloughs away. The case reported supports this explanation: the strangulation of the blood-vessels was all out of proportion to the condition of the bowel and was evidently the cause and not the result of the intussusception. The intestine opposite the strangulated mesentery was bulged, and the gut above was working down into it. The case supports the theory that intussusception is caused by paralysis of a portion of the bowel by interference with its nerve or blood supply. The article is illustrated.

Passive Pulmonary Hyperemia and Tuberculosis.—W. Tileston gives the result of a study as to the protection afforded against pulmonary tuberculosis by cardiac disease producing passive hyperemia of the lungs. His material is based on 1,900 autopsies at the Massachusetts General Hospital, 1,811 at the Boston City Hospital, and 529 at the Long Island Hospital, Boston. Mitral stenosis seemed the best form of heart lesion to study, because it is easily recognized, usually very chronic in its course, and accompanied with marked hyperemia. Only pronounced cases of this type were selected; all children under the age of twelve were also excluded. The figures obtained indicated to him very clearly that mitral stenosis affords a marked relative immunity against pulmonary tuberculosis, which is in proportion to the grade of the lesion, and that if infection does take place it usually runs a mild course, with a strong tendency toward cure. He discusses the various possibilities and theories accounting for this immunity, and says that a process of exclusion leads us to the belief that the active agent in this immunity must be passive congestion of the lungs. Bier has shown that such passive congestion has a marked action to check inflammations due to the tubercle bacillus as well as the ordinary pyogenic bacteria, which is apparently largely due to certain substances in the blood serum, the so-called alexins and antibodies, partly, no doubt, to the leucocytosis induced in the congested tissues. In the lungs the increase of connective and elastic fibers may play a part. The question is of practical importance, both as to prognosis and treatment, especially the latter. Tileston notices in this connection the attempts that have been made to produce artificial hyperemia of the lungs, and particularly the recent experiments of Kuhn with his mask, impeding inspiration and producing lung congestion by aspiration of blood from the right side of the heart into the lungs. Decided benefit has been reported from this method and actual cure claimed for favorable cases. A more extensive trial, however, is needed before a final opinion can be given as to the value of the method.

The Lancet, April 4, 1908.

Delayed Chloroform Poisoning; Its Nature and Prevention.—W. Hunter discusses this question and concludes that in delayed chloroform poisoning cases, the main trouble is a disturbance in fat metabolism in relation to hepatic function. Such a disturbance is seen also in acute yellow atrophy. The author believes that the vomiting occurring after administration of anesthetics is not of nervous origin, but essentially toxemic, due to the profound depression of liver function with consequent

diminution of its antitoxic function during the period of the administration. This depression will be the greater if a liver already weakened by disease or by poor nutrition be further unduly weakened by food having been withheld for many hours before the administration. This enforced abstention from food before administration of an anesthetic may thus in individual cases be carried too far, and it is, in the author's opinion, largely responsible for the fatal effects of delayed chloroform poisoning in exceptional cases. Such effects could in all probability be completely prevented if, instead of withholding food, particular care was taken that the patient had always a very nutritious and easily digestible meal, well-sweetened, two or three hours before the operation.

Bacteriology of Scarlet Fever.—H. Kerb tabulates the results of his observations. In general, they suggest the fact that no particular strain or variety of streptococci is more frequently present in scarlet fever than in other catarrhal and inflammatory conditions of the throat. All that has been definitely proven thus far is that the infecting agent, whatever it is, is present in the pharyngeal mucus. If none of the streptococci in the throat are causative of the primary condition, some other agent must have made it possible for them to obtain entrance to the tissues in order for them to produce the secondary complications. Staphylococci in the air passage are relatively increased in scarlet fever.

The Tuberculo-Opsonic Index of the Urine and Sweat in Health and in Tuberculous Disease.—The paper of J. Miller is largely in tabulative form and cannot be easily abstracted. It may be said that comparisons under the conditions implied in the title, showed that the opsonic index of the urine from a diseased person, unlike that of a healthy person's urine, was usually found to be lower than that of the blood (out of 50 estimations there are only six exceptions); secondly, that it was for the most part lower than the opsonic index of a healthy person; and thirdly, that frequently a rise in the opsonic index of the patient's urine was associated with a fall in the opsonic index of the blood serum and *vice versa*. This feature was present in twenty out of fifty consecutive observations. When the urine was dialyzed and then examined the same phenomenon—viz., rise in opsonic index—was present as had been remarked previously in the case of the healthy person, with this difference that the rise was not nearly so marked nor so constant as in the case of the healthy individual. In regard to examinations of the sweat, it may be sufficient to record that a number of observations on the sweat of persons suffering from acute pulmonary tuberculosis have been made, and that the samples were in every instance found to contain tuberculoopsonic substances, sometimes in surprisingly large amounts. Compared with the opsonic index of the blood serum of a healthy person, the samples of sweat were found to show indices ranging from 0.8 to 1.3. It seems evident from the author's results that the excretions—urine and sweat—contain antibacterial or bacteriotropic substances. Why such important substances should be thrown out in the excretions is a difficult problem, unless it be that being specific and not required in the ordinary functions of the cells of the body, they are therefore eliminated as foreign substances.

British Medical Journal, April 4, 1908.

Toxic Effects of Petrol Fumes.—C. R. Box refers to the cases of two chauffeurs who were shut up in a poorly-ventilated garage while the engine of their car was still running. In the course of half an hour they felt some vertigo and constriction of the head as they stated later, and three-quarters of an hour later they were found unconscious. They were immediately taken outdoors and cold effusions given. Both men were then in a completely dazed condition, with medium-sized, active pupils. They were unable to stand. One was pale, shivering, and drumming his feet on the floor. He did not appreciate what was said to him, resented interference, and struck out when addressed. The other was deeply flushed and slightly cyanosed. He was more sensible, but when moved he struck out at the door, injuring his knuckles. The pulse in each case was small and rather fast. There had been no vomiting, and the fact that one was found in the lavatory was due to his having taken a pill previously. They were again carried upstairs and laid on settles near the fire. The windows were widely opened. Although warmly wrapped up, they continued to shiver acutely for some time. The shivering had the appearance of clonic spasm, and was particularly marked in the case of the pale patient; the feet in his case and the hands in the other were constantly beating against the floor. The flushed and younger of the two recovered rapidly, the pale one more slowly. By the next day they were both all right, but had only an imperfect recollection of what had happened subsequently to their leaving the garage proper and going upstairs. The treatment adopted was free ventilation and the administration of hot strong tea, which was handy. The kindness of a bystander had already supplied a glass of spirits.

A Specific Treatment of Leprosy.—Professor Deycke, late of Constantinople, recounts his experience in the isolation from leprosy cases of a certain streptothrix. The relations between it and the genuine lepra bacillus are conjectural. From the streptothrix cultures a neutral fat called by the author "nastin" was isolated, and injections of this substance into leprous tissue caused more or less intense inflammatory swelling and softening, suppuration and necrosis of the tissue to which its action was strictly limited, adjacent areas of sound tissue not becoming affected. This reaction always occurred with pronounced participation of leucocytes. The next problem was to find some substance which would produce such an effect on the leucocytes that the nastin would give its characteristic reaction. Such a compound was found in benzoylchloride. Benzoyl itself seems to be the really active substance which acts directly on the lepra exciter. It requires, however, in order to get at the baccilli at all and not to be wasted in other directions, the guidance, so to say, of the otherwise thoroughly passive nastin, which charges itself in oily solution with benzoylchloride; it is not, however, a chemical union, but rather a state of simple solution; in this way benzoylchloride is protected from being prematurely and uselessly used up. The nastin is carried to the lepra baeilli, to which, owing to its near chemical and physical relation, it attaches itself, and then benzoyl can fully display its antibacterial action in the fat-removing sense. When deprived of fat the lepra bacilli seem to be doomed; the human organism then effects with comparative ease the further dissolution and ultimately the complete destruction of the bacteria nuclei. The conclusions drawn from the author's experience hitherto are summed up in the short sentence: Benzoylnastin is an agent which directly acts on lepra bacilli. This sentence expresses the advantages and the progress affected by his method of treatment of leprosy as compared with other therapeutic endeavors.

Electrolysis in Tic Douloureaux and in Spinal Sclerosis.—Dawson Turner calls attention to the value of electrolysis in the maladies named, and summarizes the clinical histories of seven cases. In all the results were eminently satisfactory. The author says that in treating cases of the first-named malady by this method when strong currents may be pasing through the brain, it is very important to avoid all abrupt changes in the current strength, or giddiness, faintness, or other serious symptoms may follow. Burns will also be produced if the current density be allowed to become too great. Beneath each electrode several layers of unmedicated lint soaked in the solution it is desired to use should be placed. In all these cases the treatment was the same; the salicylic ion (or the quinine ion) was introduced into the cellular tissue beneath the skin by a strong constant current. Turner adds that in the hitherto irremediable and hopeless cases of spinal sclerosis something can now be attempted, not to directly regenerate destroyed nerve tissue, though indirectly some such effect may possibly be produced, but to loosen and remove the fibrous tissue which may be pressing upon and interfering with the function of the nerve strands and cells.

Writer's Cramp.—N. Vaschide says that the act of writing demands motor corordination and a special mobility of the hand. In fixing the hand to hold the pen there is a tonic condition, while in writing the act is clonic. The interossei, the long extensors, and the long flexors are all involved in the act. The condition called writer's cramp varies much in severity and in form. In some cases there is a veritable spasm of the muscles, in others only a sense of fatigue. We know practically nothing of the pathology of this affection and little of its etiology, and hence the treatment is eminently unsatisfactory. There is rarely true paralysis, but rather functional impotence and paresis of the muscles. The contractures are produced as soon as one attempts to write and disappear under other circumstances. There may be trembling of the muscles. The prognosis is bad, since all means used fail to cure. The only treatment of real value is one that substitutes the use of other muscles for those that are disabled by using the pen in a different way or using some device that varies the muscles acutely.—*Gazette des Hôpitaux.*

Book Reviews.

THE LIFE OF NATHAN SMITH DAVIS, A.M., M.D., LL.D. 1817-1904. By I. N. DANFORTH, A.M., M.D. Illustrated. Chicago: Cleveland Press, 1907.

THE life of Nathan Smith Davis, physician, teacher, leader of medical men, and pioneer in medical education and organization, makes interesting reading as an integral part of the history of medicine in this country. No better biography could be desired than the present one, in which Dr. Danforth lovingly and reverently traces the life and work of this physician whose name carries so much that is reminiscent of the earlier years of American Medicine.

Dr. Davis was one of the founders of the American Medical Association, which he happily saw flourish from a modest beginning to a great and representative body. As a leader among leaders in medical organization, an active organizer of congresses and conventions, a writer on ethics as applied to the medical profession, and an ardent supporter of temperance and other public causes, the name of Dr. Davis has come to be known throughout the world as that of a representative American physician. In kindliness and uprightness of character, in multiplicity of interests, in energy and perseverance there were few like him. It is truly regrettable that he did not live a few years longer, for possibly if he had, and his wise and temperate counsels had continued to prevail, the past four years in the history of the American Medical Association would have been marked by quite different events than have transpired under the present rule.

CANCER OF THE RECTUM, Its Surgical Treatment, with an Appendix of 380 Cases. By HARRISON CRIPPS, F.R.C.S., Senior Surgeon to St. Bartholomew's Hospital, Member of the Council, Royal College of Surgeons, etc. Fifth Edition. London: J. & A. Churchill, 1907.

IN this, as in previous editions, the author takes up in great detail the anatomy of the rectum, together with the etiology, pathology, symptoms, and differential diagnosis of cancer of this organ. Much of the new material is in the chapter on treatment. Excision by either the perineal or transsacral route, colotomy, and palliative measures are each discussed in detail. The writer condemns end-to-end suture after excision, and favors leaving the proximal end of the gut free. Colotomy should always be done as soon as any evidences of stricture appear, and Cripps thinks it a delusion to suppose that a colotomy necessarily means that the feces are constantly being discharged, for most of his patients seem to have had a fair degree of control over the stool. In the present edition the author adds a table of 380 cases taken from his private practice, in which the duration of symptoms, the height of the disease above the anus, the form of treatment employed, together with the immediate and ultimate results, have all been carefully noted. The book constitutes an excellent treatise on this not uncommon disease.

DISEASES OF THE NOSE AND THROAT. By HERBERT TILLEY, F.R.C.S., Surgeon to the Ear and Throat Department, University College Hospital, etc. With one hundred and twenty-six illustrations. London: H. K. Gowers, 1908.

PRACTICALITY is the keynote of this book, which represents the views of one of London's ablest and most active clinicians. Debatable matters relative to etiology and pathology receive less attention than do symptoms, diagnosis and treatment. References to literature are scanty. Many plans of treatment receive little or no mention because the author frankly says he has an equally limited experience with them, and he advocates in the main what he has found to be satisfactory in his own practice. Plates and type are alike clear, the former unusually so. The author belongs to the conservative school, but has presented a book which gives a practical working guide to diseases of the nose and throat. In the matter of direct statement, Dr. Tilley's style might well be commended to some of his present-day fellow writers.

FIVE HUNDRED SURGICAL SUGGESTIONS. Practical Brevities in Surgical Diagnosis and Treatment. By WALTER M. BRICKNER, B.S., M.D., Chief of Surgical Department, Mt. Sinai Hospital Dispensary, New York; Editor-in-Chief *American Journal of Surgery*, and Eli Moschcowitz, A.B., M.D., Assistant Physician, Mt. Sinai Hospital Dispensary, New York. Second Series. New York: Surgery Publishing Company, 1907.

THE favorable reception accorded to the first edition has tempted the authors to put forth a second containing further "suggestions" sufficient in number to make up the five hundred which give the book its title. Just why valuable suggestions should be limited by this arbitrary number it is difficult to say. It cannot be denied that many valuable hints are thus presented, but just under what circumstances any one would make use of the information contained is not so easy to see. The little book is attractively gotten up and the material satisfactorily arranged for those who can derive benefit from a catechism of surgical "don'ts."

LIGHT AND X-RAY TREATMENT OF SKIN DISEASES. By MALCOLM MORRIS, F.R.C.S. Ed., Dermatologist to King Edward the Seventh's Hospital for Officers, Surgeon to the Skin Department of the Seaman's Hospital, Consulting Surgeon to the Skin Department of St. Mary's Hospital, and S. ERNEST DORE, M.D., Cantab., Assistant in the Skin Department of the Middlesex Hospital. With twelve plates. Chicago: W. T. Keener & Co., 1907.

THIS little volume of 170 pages is valuable because, in the first place, it records the personal experience of the two authors; further, because the authors do not consider their method the only way to treat certain skin diseases, nor are they unduly enthusiastic. Their aim seems to be, not to publish cures so much as to record observed facts and to help the reader to form an accurate estimate of the value of the several methods described. The authors give a careful description of their technique and also a number of cases with the results obtained. In their hands the Finsen light and the *x*-rays have given good results in properly selected cases. But they fairly admit that many cases are not suitable to the treatment herein described, and also that in many other cases so-called cures turn out not to be cures at all. The book is practical and conservative and is characterized throughout by honesty of purpose and sobriety of statement.

ATLAS AND TEXT-BOOK OF HUMAN ANATOMY. By Dr. JOHANNES SOBOTTA, Professor of Anatomy in the University of Würzburg. Edited, with Additions, by J. PLAYFAIR MCMURRICH, A.M., Ph.D., Professor of Anatomy in the University of Toronto; Formerly Professor of Anatomy in the University of Michigan. Volume III. Vascular System, Lymphatic System, Nervous System, and Sense Organs. With 297 Illustrations, Mostly in Colors. Philadelphia and London: W. B. Saunders Company, 1907.

THIS is the concluding volume of an excellent Atlas of Anatomy, the value and scope of which have been discussed in the reviews of the earlier volumes in these pages. It is difficult to speak of the plates without seeming extravagance, for they are as nearly perfect pictures of the parts as they are shown in a skilfully made dissection as it is possible to make. They are, of course, ideal, for no dissection could show the veins, blood-vessels, lymphatics, and other delicate structures so distinctly as they are here represented, but they recall vividly and make even more clear what one has seen on the dissection table. The work is not a dissection manual, for the plates are too handsome to be smeared with the soiled fingers of the worker in anatomy; neither is the text adapted to the needs of the young student. It is essentially a post-graduate work, one for the surgeon and the physician to keep on his shelves for reference, and even for study, when his practical work on the cadaver is ended.

A TEXT-BOOK OF PHYSIOLOGY. By ISAAC OTT, A.M., M.D., Professor of Physiology in the Medico-Chirurgical College of Philadelphia. Second Revised Edition. Illustrated with 393 Halftone Engravings, Many in Colors. Philadelphia: F. A. Davis Company, 1907.

THIS second edition of Ott's Physiology is a great improvement on the first, issued three or four years ago. It is bettered not only by revision of the original text, but by the addition of much new and important matter, and in its present form compares favorably with any of the older established treatises on the subject. In this edition, the sections on vision and on electrophysiology have been rewritten and enlarged, and nearly every section has been revised and emendated. The size of the book has been considerably increased, and over two hundred illustrations have been added. But even with this increase in size, many of the subjects are treated too briefly. Indeed, physiology has become so extensive a science that the attempt to treat it in a single volume, a large part of which is taken up with unnecessary illustrations, must perforce be unsatisfactory. There is no middle ground between an elementary work, in which bare facts are stated without explanation, and a voluminous treatise. The present work occupies this middle ground as well as it is possible to do so, but, like all of its class, it leaves the student with his desire for complete knowledge of the subject unsatisfied in many directions. This is not intended as a criticism of this particular book, but of similar works in general. Taking into account the limitations imposed by the vastness of the subject and the necessity of covering it in a single volume, it must be admitted that Dr. Ott has accomplished the task as well as any of the others who have attempted the impossible.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 5, 1908.

THE VICE-PRESIDENT, DR. ROBERT ABBE, IN THE CHAIR.

THE evening was devoted to a discussion of nutrition in typhoid fever.

Metabolism and Diet in Typhoid Fever.—Drs. WARREN COLEMAN and P. A. SHAFFER presented this paper. It was remarkable how little scientific work had been done to determine the most suitable dietary for typhoid fever patients. One was struck by the paucity of communications on this subject until the very end of the last century. The history of diet in fevers was ordinarily divided into two periods, the period before, and the period since Graves (1835). The attitude of the profession and the laity of the first period toward feeding fever patients crystallized itself into the well-known adage "stuff a cold and starve a fever." Under this doctrine little besides water, and very little of that, was allowed to patients suffering from any form of fever. It was through Graves' teaching that a revolution in the treatment of fevers was started. Graves convinced himself that, from want of food, the ill effects of starvation were added to the ravages of the disease, and he recommended a diet which marked a great advance in the treatment of fevers, though it was inadequate, containing about 300 calories. No further advance was made in the feeding in fevers until about 1870 when milk was substituted for the carbohydrate-water-broth-diet. The largest quantity of milk which the average typhoid patient could take in twenty-four hours, two liters, furnished even potentially only about one-half of the required energy. Actually then the teaching of Graves resulted only in changing the condition of the typhoid patient from complete to partial starvation. It was in the last decade of the nineteenth century that a few clear-sighted practitioners began to question the suitability of the milk diet. The advocates of a varied diet had not secured a large following. The central issue in the discussion was the amount of food necessary rather than its physical state. The approximated food values of the so-called liberal diets were little if any in excess of a strict milk diet. He concluded that fever *per se* was not a contraindication to sufficient food. The relation of relapses to diet must be considered from two distinct points of view. 1. Whether a varied diet during the febrile period increased the tendency to relapses. Relapses were common on a strict milk diet. The advocates of the varied diet claimed that relapses occurred less frequently in their cases. It was possible that in both series of cases relapses had been more common than was necessary. The true cause of a relapse in typhoid fever had not yet been discovered. 2. Whether a sudden change from a milk diet in early convalescence might cause a relapse. Abrupt changes in diet, especially the addition of meats, caused the well known *febris carnis*. It was not impossible that in typhoid fever the sudden alteration in diet might temporarily reduce immunity through metabolic disturbances, sufficient to bring on a relapse. All agreed that the following were required for typhoid fever patients: (1) The quantity of food, whatever latitude was allowed in variety, must be sufficient to meet the demands of the body for energy. None of the diets previously recommended had contained a sufficient number of calories. (2) Foods likely to cause mischief must be prohibited. This would include foods which were not easily digested, foods likely to ferment, and foods which left too large or a harmful residue. In nearly all of the diets previously recommended more attention had been devoted to increasing the variety of foods which might be allowed than to the dynamic value of the diet as a whole. The deficiency of the milk diet was not in its protein content, but in its insufficient dynamic value. Dr. Coleman here referred to some charts which showed the results of some studies made with milk, cream, milk-sugar, and eggs. Chocolate, vanilla, and coffee were used as flavors. Lemon juice was used as a vehicle for some of the milk sugar. In order to obtain the requisite number of calories and yet keep the bulk of the food within bounds, it was necessary to employ some form of sugar and fat. Fat was apt to cause diarrhea if increased beyond a certain point. Milk sugar was preferable to cane sugar since it was less likely to ferment or overflow into the urine. The quantity of milk sugar they gave was large, often reaching 400 to 600 grams a day. The necessity of using such large quantities of milk sugar constituted the chief practical difficulty they encountered, but with the continued help of Miss Cutler they expected that it would not prove insurmountable. (3) The food must be made as appetizing or at least as unobjectionable as possible. In conclusion Dr. Coleman said that the problem they set for themselves last summer was to study the principles of nutrition upon which the proper diet for typhoid fever patients might be constructed. They felt that they had proven that on any of the diets previously proposed the typhoid fever patient received approximately only half the food he required. In future it would be their aim to arrange a series of diets which would furnish all the energy needed and at the same time be sufficiently varied to relieve the unfortunate victims of the disease from the monotony of milk.

The second part of the paper was devoted to the more strictly scientific aspect of the work. The authors first considered the general question, whether or not they should attempt adequately to feed a fever patient. Should they supply to the fever patient, by food, all of the energy required for his life process, or should they compel him to obtain his energy, or a part of it, from the combustion of his own body material? There should be but one opinion on this general proposition, that unless there were definite contraindications in the specific disease, they should strive toward a constant replenishment to the organism of all of the energy used up. Starvation, whether complete or partial, was harmful, even in health; if starvation was harmful in health, why should it be beneficial in disease? They cited experiments to show that the digestive and absorbing capacity of the typhoid patient was, for practical purposes, very little lower than normal. But in spite of these experiments, most clinicians absolutely refused to believe that a subject of typhoid fever could digest as much or as well as a normal person, and the opinion of the clinician on this point was undoubtedly correct. Other experimenters cited by them had proved that the average typhoid fever patient, even though he had no appetite and had diarrhea, was still able to digest and absorb fairly completely, certain carefully chosen and easily digested foods. There seemed to be some basis for the fear that the intake of food in fever might tend toward an increase in body temperature. According to Hoesslin's observations the increase of temperature after a liberal diet in typhoid was at most 0.2° to 0.3° C. There appeared to be no good reason why they should not at least make an effort to supply to the fever patient as much energy as he was using up to carry on his body functions. How much energy, in terms of calories, must be supplied? According to numerous experimenters the starvation requirement for a normal man at rest was between 30 and 35 large calories per kilo body weight; or for a man weighing 70 kilos, about 2,300 calories. But the average typhoid fever patient was not at complete rest. In fevers Krehl stated that there was an increased heat production averaging 20 per cent. Twenty per cent. of the starvation requirement added to the 2,300 calories gave about 2,700 calories. To this, according to Rubner, 10 per cent. of the starvation requirement should be added to make up for the dynamic stimulation of metabolism

caused by food, and this gave between 2,900 and 3,000 calories, as a fairly conservative estimate of the daily caloric needs of the typhoid fever patient weighing 70 kilos. Few, if any, in the medical profession fed their typhoid fever patients enough to meet this minimum requirement of 3,000 calories. One of the most constant accompaniments of fever was the increased breaking down of body protein and body fat, resulting in varying degrees of emaciation. The loss of protein from the body fluids or cells was of serious importance, and should if possible be prevented. They then analyzed the possible causes for this loss of body protein. This loss from a typhoid fever patient, receiving the usual insufficient diets, was possibly the result of at least three factors: (1) The loss due to partial starvation. A normal individual would usually lose body protein if he received only 1,000 or 1,500 calories. (2) The loss due to the increased protein metabolism caused by the fever temperature. (3) A loss which apparently might not be explained by the first two factors, and which was called the toxic deduction. It was obvious that the loss due to starvation could be stopped by sufficient food; and according to the experiments cited from Voit, it should be also possible to stop, by an excess of food, the loss due to the increased temperature. Theoretically it remained to determine whether they could stop or retard the toxic destruction. The diets at present used by the clinician were not sufficient to prevent even the loss due to starvation, to say nothing of the losses due to the other factors just mentioned. For practical purposes it was only necessary to determine how much the loss of body protein by the average typhoid patient, who received a diet containing 1,500 calories, could be lowered by any dietary régime. In formulating a fever diet they should bear in mind that one object was to spare the body protein as far as possible. The three classes of foods did not have the same value in sparing protein. The high protein-sparing effects of carbohydrates was a strong reason for choosing this class of foods as a basis for a fever diet. Carbohydrates would have a much smaller effect in increasing heat production, or in raising the body temperature, than either fat or protein. For this reason Rubner suggested the substitution of carbohydrates as the chief source of energy in the diets of fever patients. A large amount of fat was objectionable because of its tendency toward digestive disturbances and diarrhea. Protein should be kept at the minimum effective amount, because of its high specific dynamic effect upon heat production and because of the large amount of work which it threw upon the kidneys. These were the considerations which had governed their choice for a diet for typhoid fever. Their plan had been to give as much carbohydrates as possible, and to keep the diet as rich in calories as possible. Their investigations were by no means completed, but their results seemed to justify the belief that a great deal could be accomplished in reducing the loss of the body protein by the use of diets containing what appeared to be a great excess of calories. In conclusion the point they wished to emphasize was that a fever patient who received a diet containing between 3,000 and 4,000 calories, chiefly in the form of carbohydrates, would lose much less body protein than if he received only 1,000 to 2,000 calories. On such a diet, with about 70 grams of protein, he might even gain several grams of nitrogen per day. A diet of this sort was necessary in order to maintain the nutrition of the patient at the highest level. It remained to be determined what effect this very high caloric dietetic treatment might have on the course and outcome of the disease. But in the absence of further experience it seemed logical to believe that maintaining the nutrition of the patient might better assist him in his defence against the disease, might hasten convalescence, and might perhaps tend to prevent certain sequelæ.

The Limitations of Liberal Feeding in Typhoid Fever.—Dr. Morris Manges read this paper. He said that the movement to feed typhoid fever patients more liberally had its origin in Russia in 1880. It was not until 1898 when Buschuew presented his startling results that any real notice was taken of the extensive work which had been accomplished in this field by the Russian physician. Buschuew stated that no one who had tried to feed typhoid patients freely would ever regret it and moreover he would never see the severe types which were encountered under deficient feeding. This enthusiast has an experience with 398 cases with only 34 deaths, a mortality of only 8.6 per cent. With such a literature and with such results from liberal feeding it was with considerable surprise that one turned to the last encyclopedic article on typhoid fever, McCrae's contribution to Osler's Modern Medicine. It would appear that this latest work on the treatment of typhoid fever recommended a diet which was very low in caloric value, 36 ounces of milk, 720 calories; 12 egg whites, 180 calories; a total of 900 calories. The adult standard given by Nichols for an average adult typhoid fever patient equaled 2,600 calories. Friedrich Müller of Munich, as a result of his experience in 87 cases, became a most ardent champion of liberal feeding, and he stated that the best method at their disposal was to feed the patient as freely as possible and to thus neutralize the diastrous effects of the autophagia which caused a total loss of 250 gm. of muscle every day. He also agreed that the danger of perforation was not increased by the giving of non-liquid food, provided it was properly prepared. The mortality in his 87 cases from perforation or peritonitis was nil. His mortality was 11 cases (13.7 per cent.), and not one of the deaths, however, was due to the diet. When in addition to all this they could quote the statistics so carefully collected in 1907 from various sources by Nichols of 1,518 cases of typhoid fever treated with the enlarged diet with only 104 deaths, a mortality of 6.9 per cent., might they not say that was a method of feeding which at least deserved mention? Dr. Manges said he did not wish to be misunderstood; it was not necessary to feed all patients liberally. If milk agreed with the patient it should be given freely; if the patient was not hungry and was doing well there was no reason why the orthodox plan should not be followed. If the same energy which was now so urgently desplayed in forcing water was at the same time devoted to forcing some properly prepared food of the kind already so frequently described as constituting the liberal diet, the subsequent course of the disease would be favorably influenced, especially in lessening the danger of late complications. Fuller nourishment would make the task of feeding less burdensome to the patient, for the frequency of the meals could be reduced and some additional rest could thus be afforded to these much disturbed patients. They all knew how Pawlow had insisted on the influence of taste and relish upon digestion, and the value of chewing and salivation upon the same. Both these indications were fulfilled by the liberal diet. Dr. Manges warned against any fixed plan of liberal feeding. No two patients were alike, nor were the successive stages of the disease the same. Individualism was an essential requisite in feeding typhoid fever patients. That all feeding should be reduced or suspended in severe vomiting, bleeding, peritoneal irritation and suspected perforation required no special mention. He directed attention to the advisability of reducing the amount of food when sloughs were abundant in the stools, for then there was the greatest danger from hemorrhage or perforation. In conclusion Dr. Manges quoted a few paragraphs from Flint's "Practice of Medicine," published forty-two years ago. These paragraphs were printed unchanged in every edition of this work. Although Flint recommended milk and fluid diet, yet the underlying principles were the very ones upon which those who believed in the liberal feeding based their claims.

Dr. Graham Lusk said that twenty years ago when he was in Munich he took a diet containing 20 grams of

nitrogen and 500 grams of carbohydrates. When the 500 grams of carbohydrates were left out, the nitrogen in the excreta arose, showing that in a normal person the carbohydrates protected the proteids. When he returned to this country the thought occurred to him that possibly proteid metabolism in fevers might be lessened or stopped by giving a diet rich in carbohydrates. At the New Haven Hospital a standard diet of milk with a certain percentage of sugar was tried, but the figures obtained from each day's sample of urine were so misleading that the experiments proved nothing. A high carbohydrate diet did protect large proteid waste. Tuberculosis was treated by giving four quarts of milk and a number of eggs a day, with a probable total of 30 grams of nitrogen; this represented an enormous quantity of proteid and Dr. Lusk said there was no scientific work anywhere which showed that this was either necessary or advisable.

Dr. C. G. L. Wolf said that for the last three years he had been engaged with Dr. Ewing and Dr. Lambert in a study of the infectious fevers from another standpoint, the investigation of the nitrogen and sulphur metabolism as represented by an analysis of the urine. For the purpose of this work it was necessary to employ a diet of constant composition. In their first experiments they employed a diet containing very little protein, but whose heat value was mainly made up of fat and carbohydrate. The caloric value of this food was about 2,000 calories. Their food was not only low in heating power but contained sufficient protein. He was struck by the large loss of body protein which they encountered. In the pneumonias a nitrogen loss by the urine of 30 grams was not infrequent; this meant a loss of muscle tissue of over 600 grams, a pound and a quarter, a day. The typhoid cases also gave similar results, although not so marked. In the pneumonias, after the crisis, the nitrogen loss dropped with remarkable suddenness. This showed that while the diet was adequate during convalescence, it was in no way sufficient when the toxemia was at its height. He had not the slightest doubt that had the diet furnished a heat supply of 3,000 or 3,500 calories with an adequate supply of protein, they would have converted the loss of body tissue into a gain. In times of epidemics the large percentage of the mortality fell on the underfed. In these instances one was dealing with subjects receiving insufficient heat supply and minimal quantities of nitrogen. The death rate of the inadequately fed Asiatic was incomparably greater than that of the European exposed to the same source of infection. The experimental evidence of the effect of undernutrition on the resistance to toxic agents was also distinct. There seemed to be no doubt that the loss of body proteid acted deleteriously in two ways; first, in the production of a toxic condition or toxic products, and secondly by lessening the resistance of the patient to the infective process. If this was so, every effort should be made to prevent this loss, and Dr. Coleman and Dr. Shaffer had clearly pointed to the method.

Dr. W. Gilman Thompson thought that the contributions to the study of metabolism and diet in typhoid fever by those who read papers marked a very important beginning in the work. He said he had seen almost every kind of food tried in typhoid fever. Twenty-five years ago they gave an exclusively milk diet, and the milk was continued ten days after the normal temperature was reached. They then were imbued with the idea of over-feeding; on the contrary, the patients were underfed. Six years ago milk sugar was used. They also used fats. They tried cream and cod liver oil in the latter stages of the disease, and then had difficulty because of the flatulent dyspepsia which developed. Then carbohydrates were tried, egg albumin and water, etc. It was a noteworthy fact that the best nourished patients were the hardest hit in this disease. Such a patient was likely to have a hard time of it, and apt to be extremely ill, to have relapses and complications. His experience had proven that when typhoid fever patients had had a high temperature for five, six, or seven weeks, they would improve very much on a liberal diet. Patients should have a good digestion, there should be an absence of meteorism, and he believed it was best to give as liberal a diet as they could digest, largely of milk, but reinforced by gruels.

Dr. Egbert Le Fevre said that an exclusive milk diet was an unsuitable one for the average typhoid fever patient. Some years ago it was shown that to obtain a sufficient number of calories from milk it was necessary to give so much milk that the patients could not tolerate it. Since using a liberal diet in typhoid fever patients he had been much gratified at the results. Much of the fermentative condition and diarrhea was due to the excessive amount of milk given. If the stools were examined a cause for the flatulency would be found. Dr. Le Fevre said he tried to take two quarts of milk a day and nothing else, and the lesson learned was kept in mind when ordering milk for a patient. Patients could not tolerate large quantities of milk. On the other hand, they could tolerate mixed feeding where carbohydrates, albumin water, and milk were more or less alternated. In post-typhoidal sepsis, where the patients ran a temperature for a long time but without definite typhoidal symptoms, with progressive emaciation, a more liberal feeding was indicated.

Dr. T. C. Janeway believed that the papers presented a clear argument for the use of higher carbohydrate diets in such diseases as typhoid fever, but yet no clear statement was made as to how to apportion the proteid content. The objections to the use of milk sugar were hard to overcome; although a considerable amount might be given in lemonade, yet many patients would reject this. To fortify with cream was easy of accomplishment.

Dr. James Ewing said that the loss of the body nitrogen was of scientific interest and should be examined chiefly from two points of view, as bearing first upon the therapeutic control of the disease, and, second, as bearing upon the pathology of the disease. They were now accustomed to suppose that typhoid fever resulted from a growth of bacilli in the body as in a test tube, and the severity of the disease depended upon the virulence of the bacilli. There was something in this view. The typhoid bacillus varied a great deal in virulence and in the numbers found in the body. But on the other hand, the body itself varied a great deal; he believed there was good pathological and clinical evidence to show that variations in typhoid fever depended upon the variations that were established in metabolism. When typhoid fever was studied chemically it would be found that the severest cases showed the greatest loss of nitrogen, and the severity of the disease could be estimated by the loss of nitrogen. As a measure of the severity of the typhoid fever, a study of the typhoid bacillus itself was not reliable, but a study of the nitrogen loss was more reliable. The majority of the cases died from autointoxication; some died rapidly with or without disagreeable symptoms. There were certain definite conditions which might arise as complications, and one was acute yellow atrophy of the liver, and in this there was a disturbed metabolism. If metabolism could be controlled by a proper diet, it would eliminate a certain number of these particular cases. It was well known that very well fed patients did badly; Dr. Ewing said of course they did; they lost sixty or seventy pounds of flesh in three or four weeks. As a rule very fat patients did badly. In any condition where the body fat had to be burned, the ordinary nutrition was turned into starvation; here the prognosis was bad. The sudden burning of the body fat was dangerous. This might be eliminated by choosing and administering carbohydrates.

Dr. Coleman wished to make it plain that they were not advocating any particular dietaries; the work had not progressed far enough for that. They hoped to be able to arrange a dietary in the future.

Stated Meeting, Held March 19, 1908.

The President, Dr. John A. Wyeth, in the Chair.

The Physiological Mechanism of Vasoconstriction and Vasodilatation.—Dr. George B. Wallace read this paper. (See p. 673.)

The Therapeutics of Vasoconstriction and Vasodilatation.—Dr. Egbert Le Fevre read this paper. See p. 676.)

The Present Status of Experimental Arterial Disease.—Dr. I. Adler read this paper. Josue in 1903 reported that he had artificially produced arteriosclerosis in the aorta of rabbits by intravenous injections of adrenalin. The lesions produced were characteristic. The site of predilection was the ascending portion and the arch of the aorta. The abdominal aorta was the last to suffer. The lesions appeared as larger or smaller patches of peculiar translucent appearance and rough surface; in the advanced stages the edges were somewhat raised above the level of the inner surface of the vessel, while the center was usually depressed; the vascular walls were distinctly thinner than normal in and about these patches and thus tended to the formation of aneurysmal dilatations and pouches. As a rule calcification appeared at a very early stage of the process. Almost all investigators had found these lesions confined to the aorta, no matter how long the animals had been treated. All were pretty well agreed on the histology of these lesions. The degeneration was primarily and mainly located in the media. Dr. Adler mentioned rather a large group of substances, some tending to raise blood pressure, some having no effect at all upon it, some even lowering it, but all producing very similar effects upon the aorta of rabbits. They all primarily affected only the media, causing necrosis with degeneration and calcification of the smooth muscle fibers, stretching and breaking up the elastic fibers and, where the intima was at all affected, it was simply in the form of more or less secondary and compensatory thickening, never associated with any degeneration or ulceration. The lesions described had been obtained only in rabbits. The positive results obtained were very frequently in no proportion to the number of injections or to the duration of the experiment. Josue called attention to the fact that the age and weight of the rabbit was an important factor; that results were more apt to be positive in old animals than in the young ones. On the other hand, there were reports of old animals showing nothing, and of young animals with positive results. In view of irregular and contradictory results, the question suggested itself to many investigators: Were they really producing an experimental effect by the intravenous and subcutaneous injections? Was it not possible, nay even probable, that their so-called positive results were the natural outcome of spontaneous disease of the rabbit, and had no relation to their experimental treatment? It was beyond doubt that arteriosclerosis did occur in rabbits. In view of the startling figures brought forward by Miles, and after deliberate and careful study of all the results, both positive and negative, at present available, it might well be questioned if the aortic lesions observed were the result of experiment, or if they were not rather simply the natural outcome of spontaneous disease without any causal relation to experimental procedures. It was an almost universal consensus of opinion that pressure and tension were the main factors in the development both of the physiological and pathological alterations in the arteries, and that mechanical impairment was the underlying and primary cause of arteriosclerosis. Arteriosclerosis was found with increasing frequency as more attention was paid to the subject, in youthful individuals, and Simnitzky, who confined his attention only to the aorta, found the early stages of arteriosclerosis in individuals under twenty-five years of age in at least 27.5 per cent. of all cases examined. Arteriosclerosis might be designated as a morbid condition of the blood-vessels closely following and allied to the physiological process of development, growth, and senescence of the vascular system and governed by the same laws. Arteriosclerosis was merely the anticipation in time, extent, and intensity of the normal "physiological" condition of senility. It was an impairment or loss of elasticity and of functional adaptability of the vessel walls. Pathologically it was a process of degeneration of the elastic and muscular elements of the vessel walls, associated with compensatory and reparative hyperplasia principally in the connective tissue elements, and often leading to calcification and ulcerative processes. The recent experimental researches with adrenalin, nicotin, and all the other substances would seem to have a direct bearing upon the problem of arteriosclerosis inasmuch as they appeared to demonstrate the effect of toxins of various kinds upon the development of atherosclerotic lesions in the rabbit. They would also appear to go far towards establishing a most important fact, namely, that different kinds of toxic agents could produce lesions of different histological character. It must be confessed, however, that the element of uncertainty as to how much was due to the experiment and how much was spontaneous, very seriously impaired the value of all this work.

The Effect of Prolonged Adrenalin Medication on the Human Circulatory Organs, with Report of Case.—Drs. Harlow Brooks and D. M. Kaplan presented this paper which was read by Dr. Brooks. It was generally supposed that adrenalin caused a marked increase in blood pressure soon after its hypodermic administration; this was rarely produced when given subcutaneously. A certain amount of danger accompanied the persistent use of this agent. With regard to the vascular lesions produced by the prolonged administration of adrenalin, they resulted not only from a possible mechanical injury, but also in some other way, causing the appearance of degeneration or necrotic foci especially in the media of the vessels. The lesions produced by adrenalin in the arteries of experimental animals were not those of true arteriosclerosis as seen in man. They wished to place on record a case in which adrenalin was administered for over three years, the drug being given daily and in large amounts varying from 10 to 120 minims intramuscularly per dose. The patient suffered from bronchial asthma. During her stay in the hospital, lasting three years, she received no less than 2,000 injections, and the blood pressure taken shortly before her death showed no permanent alterations. The total amount of the drug received by her equaled forty-four ounces. She died of hemorrhagic pancreatitis. The visceral lesions were predominatingly those of an acute parenchymatous type and were apparently of recent origin for the greater part. Some of the organs, notably the liver, heart, and lungs, showed also the changes resulting from chronic passive congestion, probably of considerable standing. The lung showed in addition the typical changes of a chronic bronchial asthma. The pancreatic lesion apparently originated some weeks before death, finally terminating with an acute diffuse capillary hemorrhage and resulting necrosis. The alterations in the medulla of the adrenal bodies might be etiologically related to the adrenalin medication. The most striking feature found in the aorta and large trunks was preeminently a type of focal necrosis, which he believed to have been entirely separate and distinct from the ordinary changes of arteriosclerosis which were also manifested in lesser degree in the same vessels. These changes, and especially those involving the media, were quite similar to those produced in experimental adrenalin poisoning and they believed them to be due to the prolonged and heavy administration of this drug. They believed that the relative slight degree of these changes in a case where the drug was used so freely and for so long a time, indicated that it might be used in ordinary cases sufficiently for the average therapeutic result with relative impunity.

SECTION ON MEDICINE.

Stated Meeting, Held February 18, 1908.

DR. HERBERT S. CARTER IN THE CHAIR.

General Phlebosclerosis, Thrombophlebitis of the Left Common Iliac, Moist Gangrene of Left Lower Extremity; Amputation; Recovery.—Dr. H. W. BERG made a report of this case. He reported it for two reasons: First, because of its rarity, and, second, because of the interest attached to the complicating left hemiplegia, from which the patient ultimately recovered, due either to a thrombosis of the cerebral veins following a similar sclerophlebitis or an embolus of the Sylvian branch of the middle cerebral artery originating from a thrombus below, a portion of which, carried into the circulation, had passed from the right to the left heart through a patent foramen ovale. Sclerosis of the veins of the body or general chronic endophlebitis, similar to, although not necessarily accompanied by, general arteriosclerosis, was first observed and described by Lobstein in 1835. Martin found this condition present in 60 per cent. of all male patients over 65 years old in his service at the Montreal Hospital. But in young patients without arteriosclerosis the lesion was extremely rare. He reported a case in a patient of 24 years, whose superficial veins felt like thick, more or less rigid, calcified cords, indeed somewhat like arteries, except that the pulsation was absent. Following the report of Dr. Leo Buerger of the results of the gross and minute pathological examination of the amputated limb, he again called attention to the rarity of the condition. But a few cases of general arteriosclerosis in young men had been reported in the literature, and in these cases there was generally an accompanying arteriosclerosis. Even smaller in number had been the cases of phlebosclerosis in which the arteries had been perfectly normal, as in the patient whose history he recorded. He said that he had not seen a single case in the literature in which a phlebosclerosis, complicated by a thrombophlebitis of a large venous trunk had resulted in gangrene of an extremity, requiring amputation. Thrombosis of even large venous trunks very rarely resulted in gangrene of a whole extremity, owing to the fact that the collateral circulation very soon became sufficient to act vicariously, and even permanently, for the occluded vessel Obviously, owing to the general phlebosclerosis, the collateral veins were hardly sufficient for their usual function, and failed to undergo the dilatation and enlargement necessary for an efficient collateral venous circulation. That the patient suffered from thrombosis of the left common iliac vein was shown by the fact that not only were the edema and swelling and the superficial dilatation of the collateral veins marked in the affected leg, and particularly the thigh, but there was marked edematous infiltration of the left side of the anterior abdominal wall and loins. Indeed the slight swelling of the other leg aroused the suspicion that the thrombus had extended into the vena cava, thus interfering with the return of blood from the right common iliac. They looked for the appearance of blood in the urine to indicate the extension of the thrombus high enough up to interfere with the venous return from the kidneys, but this symptom of a passive venous congestion did not occur.

A Case of Pernicious Malaria with Autopsy.—Dr. G. R. SATTERLEE made this report, which was interesting because of the infrequency of tropical malarial fever in the northern part of this country, and the still more infrequent reports of autopsies on these cases. Temperature charts and plates were presented. He concluded (1) that this was a case of acute malignant or pernicious malarial fever of the estivoautumnal type (tertian form, according to Dr. Charles F. Craig, U. S. A.); (2) that death was caused by the overwhelming invasion of the blood by the parasite and due possibly to the toxins evolved and not to acute cerebral congestion and thrombosis; (3) that the sporulation of the organism took place principally in the inner organs, especially in the spleen, liver, lungs, pancreas, bone marrow, and, to a less extent, the kidneys; (4) that the gametocytes might not be seen in the peripheral circulating blood until just before death; (5) that alcoholism played a small part as a factor in the man's death; (6) that the diagnosis of pernicious malaria could be made on the small size, dark cytoplasm, and shrinking of the organism of the infected corpuscles.

The Life History of the Malarial Parasite.—Dr. D. M. KAPLAN presented this communication. Of mosquitos only the culicidæ were of interest to the physician. The *Anopheles maculipennis* was the direct host of the malarial organism, and he gave a few anatomical and biological facts concerning this insect. He then considered the parasite itself, and concluded his paper with a consideration of the various phases encountered during its life in the human blood. The antennæ, palpi, and stinger serve to differentiate the male from the female anopheles. In the question of malarial transmission, one had to deal only with the females, as they alone sucked blood and harbored the parasite. Of biological interest was the wide range of territory occupied by mosquitos; they could be found as far as 70° north and 50° south of the equator. The male fecundated the female and then most likely died. The males, without exception, were vegetarians; the females sucked blood from man and beast in order to complete the development of the eggs. The anopheles could hatch in sea water. The malarial parasite belonged to the class of unicellular animals, or protozoa. Of the malarial parasites there were three varieties, which he named the ordinary tertian parasite, *Plasmodium vivax tertianæ, Plasmodium malariæ quartenæ, Plasmodium immaculatum tropicum, quotidianæ* or *tertianæ*. He then described the developmental cycle of the parasite. The picture seen in the blood of human beings corresponded to the asexual cycle of the hematozoon and was known as the schizogonic period, in contrast to the sporogenic or sexually potent period in the body of the anopheles. After describing the life of the malarial parasite in the human blood, he said the sexually potent cycle took place in the stomach of the mosquito. The first manifestation of sexual activity was noted in the female organism. An active movement of the pigment took place, with a tendency to approach the periphery; then some of the pigment was thrust in a lumplike mass from the parasite and served to attract the macrogametes, which had, by this time, been thrust from the microgametocyte. In an instant the microgamete was blended with the macrogamete, only one flagellum entering one female parasite. The so-called oökinet was formed in about fifty to sixty minutes, and this had the power to penetrate through the epithelial layer of the mosquito's stomach and lodged finally between the muscular and elastic layers, where it joined on oval cyst. This stage was known as the oöcyst stage. The future development of the oökinets was marked by a direct division of the nucleus into two, four, etc., and a corresponding enlargement of the oöcyst. In the further development of oöcyst it became filled to its capacity and finally burst, discharging its contents into the body of the mosquito; its lodgment in the salivary glands was accomplished by the blood and lymphatics. In the differentiation he called attention to the fact that in the tertian type the pigment was fine, yellow-brown in color, and the red blood cells were distinctly swollen and with stippling. In the quartan type, the pigment was coarse, very dark, and in small quantity, and there was no stippling in the red blood cells. In the tropical type the pigment was very fine, was dark-brown, and in very small quantity, the red blood cells were contracted, were the color of old brass, showed stippling, and intense staining.

Report of a Case of Rapidly Fatal Diabetes.—Dr. T. C. JANEWAY reported this case, one of unusual type in his

experience. A girl of nineteen years, a student at Vassar College, had enjoyed unusual health all her life. There was, however, a history of diabetes in her father's mother, this being the only case in the family. Her parents were American. She had had nothing but the ordinary infectious diseases of infancy. In 1896 she had an attack of a short fever, in all probability typhoid. She had always been a robust girl and athletic. While in college in the fall of 1906 she was well except for an attack of tonsillitis. In the beginning of the second week in September, 1907, she noticed that she was more thirsty than usual, but she kept in her ordinary health. During the latter part of September she returned to college. On October 13 she applied to Dr. Baldwin because she was passing a large quantity of urine. She had extreme frequency of urination, was languid and drowsy. The urinary examination showed 72 ounces passed, specific gravity of 1.040, with 5 per cent. sugar, but no diacetic acid. She was placed on a supposedly strict diet. One-half a pound of gluten bread a day caused a lessening of the frequency of urination. During the last few days of her stay at Poughkeepsie she began to pass diacetic acid. On October 30, about six weeks after the first onset of any possible symptoms, she came to New York to consult Dr. Janeway's father. She vomited the morning before leaving Poughkeepsie and stated that she was short of breath when she entered the Grand Central station. In the office she had the typical Kussmaul breathing. The urine examination of a specimen representing five hours' secretion only, showed a large amount of sugar and an enormous Gerhart's reaction, showing a large amount of acetone. She was sent to St. Luke's Hospital. She vomited once or twice more. The same afternoon she had much more air hunger. She was placed upon soda both by mouth and rectum. Her temperature was subnormal. Most of the soda was retained. During the night she had severe pains in the right chest, but this could not be accounted for on physical examination. She became more and more drowsy. Her pulse was rapid. In the morning she was given an intravenous saline infusion with bicarbonate of sodium added. Caffeine salicylate was given hypodermically. She became comatose. At 2 P. M. she passed twenty ounces of urine and immediately collapsed, became cyanotic, lived one hour, and died of gradual respiratory and cardiac failure. The twenty-four-hour urine, from October 30 to 31, amounted to 1,700 c.c., with 14.9 grams sugar. Acetone was present. Only 6.8 grams of nitrogen were passed in twenty-four hours, in which 2.6 was ammonia nitrogen, *i.e.* over 31 per cent. of the total nitrogen. The division of the urine secreted in certain periods showed the effect of the soda administered on the ammonia nitrogen output. In the first five-hour period, with no soda, she passed .155 gram of ammonia nitrogen per hour. In the second period, with soda, she passed .097 gram. This showed almost one-half the amount passed when on the soda treatment. In 19 hours 75 grams of soda was given; on the next day she received 30 grams; she passed a still smaller amount of ammonia nitrogen, .072 gram per hour, but there was no effect upon the coma. She also had a trace of albumin and some granular casts. Only a few such cases had been reported in the literature of diabetes proving as rapidly fatal as this. He could not give the exact duration of the diabetes; but the girl was apparently healthy, mentally and physically, up to a certain time, and it made him feel that it dated back no further than the second week in September, this period of only three weeks being surprisingly short. Dr. Janeway passed a chart around showing the urinary findings.

Report of a Case of Diabetes with Unusual Cerebral Symptoms.—Dr. L. A. Conner made this report. The patient was an Italian girl, sixteen years old. Her family history was negative. Her earlier history was unimportant; she had always been robust and strong. She was in her usual health up to three weeks before admission to the hospital, when, without warning, she developed twitching of the right arm and leg without loss of consciousness and with a feeling of tingling in the skin. These attacks were repeated several times a day up to the time of her admission to the Hudson Street Hospital. It was also noticed that she had increased thirst and passed urine several times during the night. On admission (December 12, 1907) she was found to be a well-developed, well-nourished girl, with good color, conscious and intelligent. The chest and abdomen showed nothing abnormal. There was distinct weakness of the right arm and leg and absence of both patellar and triceps reflexes; otherwise the examination of the nervous system was negative. The eye grounds were normal. From the time of her admission to her death, thirteen days later, the patient had daily from eight to fifteen convulsions. They varied in duration from one minute to one hour. They consisted of a clonic spasm of the right arm and leg, with frequent twitchings of the upper part of the face and sometimes rigidity of the left arm and leg. There was no loss of consciousness. On the day after admission there was a positive reaction for both acetone and diacetic acid. Thereafter neither was present until the day of her death. There was no Beta-oxybutyric acid present at any time. On the day before her death the ammonia nitrogen formed 9.5 per cent. of the total nitrogen. On the tenth day in the hospital she became drowsy; this gradually deepened into somnolence and finally into coma; the temperature rose gradually and she died on the thirteenth day, less than five weeks after the first symptoms. At no time during the coma was there present the peculiar full breathing which was regarded as the usual and characteristic feature of diabetic coma. The autopsy showed an extreme degree of atrophy of the pancreas, with almost complete disappearance of the body and tail. None of the other viscera showed important changes. In the brain and medulla nothing whatever abnormal could be found on either gross or microscopical examination. Dr. Conner said that convulsions of any sort in diabetes were exceedingly rare. In the few cases reported they had almost all been of epileptiform type and had occurred in connection with a terminal coma. This case was peculiar (1) in the Jacksonian character of symptoms; (2) in the long duration of the attacks (five weeks); (3) in the apparently mild type of diabetes; (4) in the absence of the usual evidences of severe acid intoxication.

Diabetes and the Alkaline Treatment.—Dr. C. N. B. Camac reported the case of a woman who had been in the City Hospital from February until November. She showed the usual symptoms and signs of diabetes. Between February and May the sugar in the urine reached the highest, 4.25 per cent., the lowest 2.3 per cent. There was a slight trace of acetone throughout. About May 23 she began to show irritability and there was some diarrhea: the patient rejected treatment and became troublesome. As she was below the average mentally, no particular note was made of this until June 3, when she became drowsy and later showed definite stupor. She could be aroused by shaking. At that time the specific gravity of her urine was 1.030, and there was a definite acid reaction. There was present acetone, but no diacetic acid. There was apparently an oncoming coma. She was placed under the alkaline treatment with this arrangement—that if in twenty-four hours the condition developed markedly, she was to be given subcutaneously bicarbonate of soda injections; if the condition continued to deepen it was to be given intravenously. If no increase in the symptoms was noted, saline enemata were to be given, one pint every six hours, and 500 c.c. normal salt solution subcutaneously and 390 grains of soda bicarbonate in twenty-four hours by mouth. This treatment was instituted June 5. The condition did not get more marked, but she continued in a semicomatose condition for three or four days. She received the

salt solution subcutaneously and by enema and the soda bicarbonate by mouth. The percentage of sugar dropped to 1 per cent.; the reaction continued acid, and the acetone increased and diacetic acid appeared. Beta-oxybutyric acid was not present. This was on June 7. On June 10 she remained in the same condition, and did not become more deeply comatose. The acid reaction continued. The percentage of sugar was slightly raised, the acid reaction persisted, but the Beta-oxybutyric acid did not appear. The sugar remained at 1 per cent. and the specific gravity became 1,011. The reaction was slightly acid; the acetone was increased as well as the diacetic acid. One June 11 the diacetic acid disappeared, although the acetone was still present. The sugar dropped to .5 per cent. and the specific gravity became 1,009. The patient's condition on this date improved. The urine became alkaline by litmus reaction, but by more accurate test was shown to be acid. The treatment was continued, the soda bicarbonate was reduced from 390 to 90 grains in twenty-four hours. The diacetic acid did not again appear. Acetone was present but finally disappeared. On the 13th she talked freely and appeared to observe what was going on about the ward. There was at no time the Kussmaul type of breathing, but there was incontinence of urine and feces during the stupor. The ammonia nitrogen, urea nitrogen, and total nitrogen were not disturbed. The total acidity changed definitely under the alkaline treatment; the reaction became distinctly alkaline and did not become acid for a number of weeks. The points that were noticeable were the change in the amount of sugar, the change in the specific gravity, and the change in the reaction. The acetone first appeared; then the diacetic acid, with an entire absence of the Beta-oxybutyric acid. Then occurred an inverse disappearance. In association with the changes noted above, there was an unusual change in the clinical appearance of the case. There was no disturbance in the nitrogen, with the exception of the rest nitrogen, which was high. Dr. Camac said he did not attempt to comment upon this case; mild acidosis suggested itself; yet he thought some other metabolic disturbance must be considered to account for the condition. The alkaline treatment was begun before the diacetic acid appeared; this acid appeared just after the alkaline treatment was begun. Of course, it was well known that most authorities were of the opinion that the alkaline treatment, once coma developed, was of no avail. The amount of alkali received by this patient was not high. This patient continued to receive the alkaline treatment over a number of weeks and remained practically entirely free from any evidences of intoxication. She was up and about the wards. In the following October she again apparently was passing into an attack similar to that already noted. After twenty-four to thirty-six hours it was evident that this was the beginning of a hemiplegia. The feeling then was that a mistake had been made in associating the former attack with the diabetes, but this was difficult to believe in the face of the urinary findings. The patient died. At autopsy there were found lesions in the pancreas to account for the diabetes. The presence of cerebral arteriosclerosis accounted for the hemiplegia. The urine and histological specimens were independently examined at the Streeter and Cornell Laboratories and the respective findings carefully compared.

Dr. James Ewing said he had an opportunity of seeing the pancreas in these cases, which showed extensive interstitial productive inflammation with the consequent destruction of the alveoli, with but few lesions in the islands of Langerhans. The pancreas in Dr. Camac's case showed identical lesions, but less dilatation of the ducts than in Dr. Conner's case. He said he was chiefly interested in the relation of acidosis to this condition, and he thought that the data favoring the view that these comas were referable to any one or all the acetone bodies was losing ground. There was not sufficient ground for the belief that the acetone bodies were sufficiently toxic, or that their salts were sufficiently toxic or acid reaction so great as to abstract alkali from the tissues and so bring about a state of coma. The toxic effects of acetone had recently been experimented with, and as a result it had been shown that acetone occupied an intermediate position between alcohol and chloroform. It could be given in enormous doses to animals. It could not be considered as an important toxic agent in disease. In Dr. Camac's case, while there was practically no acidosis, there was a remarkable disturbance in the rest nitrogen, and what the significance was he said he did not know. But when there was 26 per cent. of rest nitrogen with 10 grains total nitrogen, the patients were sick. Curiously enough, while the ammonia nitrogen disappeared, the rest nitrogen remained high. In the beginning of the disease this 26 per cent. indicated a serious disturbance in metabolism apart from the acidosis. He was very much interested in the views held by some German workers with regard to acidosis. When the carbohydrates failed to be burnt the fats were called upon for the energy; with deficient oxidation of these fats there was brought about destruction of proteid bodies; and so they were able to interpret acidosis as an incomplete metabolism going on.

Dr. Mayer said that acetone was always found in the body, and slight quantities, from 1 to 5 centigrams, were found in the urine. An increase in the acetone was found in diseases, such as malnutrition, inanition, starvation, phthisis, and in abdominal diseases especially, particularly those of children. Whenever the carbohydrates were not sufficiently burnt, these acetone bodies were found in the urine; very often these acetone bodies could be made to disappear in disease by giving carbohydrates, if they could be burnt in the body. In the burning of sugar in the body, probably many products were produced which appeared in the urine. In diabetes sugar was not consumed in a normal manner; some sugar was always consumed, but not enough to prevent the appearance of acetone, Beta-oxybutyric acid, and other substances in the urine. One authority stated that acidosis was distinctly poisonous in diabetes, and it was that that killed. Von Noorden had attempted to prove that if the alkaline treatment was given in these cases it would cure the acidosis; Von Noorden's theory was that a definite poison was formed in severe cases of diabetes and that was what killed. Dr. Mayer called attention to the fact that Dr. Herter of this city reported the results of his experiments four or five years ago before the Section on Medicine. If there was a large quantity of acetone present, the alkaline treatment was of no avail. Dr. Mayer had tried giving certain products formed by formalin and ammonia, with the idea that they might break up in the kidney into their constituents and thus form ammonia.

Dr. T. C. Janeway took issue with the title of Dr. Camac's paper. He said he had had the opportunity of seeing this woman before and after Dr. Camac, and he felt strongly that what Dr. Ewing said was right; he did not know that the coma was due to either in diabetes or in uremia. Yet diabetic coma was a clinical entity. Dr. Camac's case was one of mild grade and apparently of long duration. He said he had a strong feeling that the coma in this case belonged to the type clinically of uremic coma or was due to some gross intracerebral changes.

Dr. Camac closed the discussion. He said the title of his paper had not been correctly given; it was not called coma. At the same time, he said, one should recognize the fact that the continental clinicians divided comas into three forms. They were beginning to doubt acidosis explanation of coma. In a short time they might be brought face to face with entirely different metabolic disturbances to explain the coma. These so-called border-line cases, where alkaline treatment had been given, should be reported, especially if they had been as carefully observed as this was. He said he had refrained from making comments upon the case; he simply presented clinical notes upon it.

Pathological Society of Philadelphia.

At a stated meeting, held February 27, Dr. W. M. L. Coplin exhibited "Skulls Illustrating the Inadequacy of Reparative Efforts of the Dura, as Compared with the More Active Function of the External Periosteum." In the two specimens shown the osteoclastic process was well advanced at the margins of the lesions in continuity, adjacent to the periosteum, covering the outer surface of the bones involved, while there was little progress in this direction on the inner surface. Dr. A. O. J. Kelly exhibited a specimen of "Carcinoma of the Stomach," from a man who presented symptoms suggestive of abscess of the liver with consecutive empyema. There were also indications of carcinoma of the stomach. An opening was made into the supposed purulent accumulation in the pleura and a moderate amount of pus evacuated. The wound was drained and a further amount of thinner fluid continued to escape. The patient died eventually, however, and post-mortem examination disclosed a cauliflower growth of the fundus of the stomach, with metastasis to the spleen, involvement of the pancreas, adhesion and thickening of the layers of the left pleura, and obliteration of the pleural cavity. The incision of the thorax had established a communication with the cavity of the stomach. Dr. M. B. Hartzell exhibited "Photomicrographs Made With Lumière Autochrome Plates." The plates are prepared by incorporating in them starch granules pigmented with the three primary colors, and they are exposed with the glass side forward, so that the rays of light are intercepted by the starch granules before reaching the sensitized medium, each color intercepting the rays of light for all of the other colors and permitting the passage only of rays of the same color as itself. A special color screen is interposed to exclude actinic rays. The result is an accurate transparent reproduction in colors, from which, however, prints cannot be made. In the case of microphotographs the exposure must be long, as much as two hours in some instances. For ordinary pictures an exposure of from two to fifteen or twenty seconds suffices. The results are eminently satisfactory, and they can be viewed by transmitted light or be reflected by means of a lantern on a screen. Pictures of patients with cutaneous lesions also were exhibited. Dr. E. Burvill-Holmes exhibited "An Organism Not Identified." It came from the body of a man who had long presented symptoms of disease of the lungs, without the presence of tubercle-bacilli in the sputum until late in the course of the disorder and after association with other tuberculous subjects. On post-mortem examination the appearances were not those commonly observed in cases of pulmonary tuberculosis, and examinations of a hanging drop and of cultures disclosed long filamentous organisms with branching, which failed to absorb the usual stains. Dr. Alfred Gordon exhibited a specimen of "spina bifida," which came from a newborn child of alcoholic parents. The formation consisted of a meningomyelocele, and it projected through a defect in the vertebral column in the lumbar region. It consisted of the spinal membranes containing the termination of the spinal cord and the cauda equina. Dr. W. M. L. Coplin and Dr. John Funke presented a communication entitled "A Preliminary Study of Hemagglutinins." In view of the disastrous effects at times observed following the transfusion of blood from one person to another for the relief of profound anemia, the endeavor was made to determine the factors concerned in bringing about the undesired results, and, if possible, to secure their elimination or avoidance. To this end the blood-serum from a case of pernicious anemia and from two others of pulmonary tuberculosis with profound anemia was brought in relation with normal blood from several sources, and the reactions studied. These were rather variable, in accordance with a number of conditions, the relations of which are yet to be determined. For example, while the blood-serum from two of the patients each caused agglutination of normal blood, the pooled serum from both failed to do so. Also the response was different when large amounts of salt solution, strong solutions of sodium chloride, were added to the serum than when weak solutions were added. Other variations of a comparable character were noted. Dr. Howard T. Karsner read a paper entitled "The Leucocyte Count in Diphtheria Before and After Antitoxin Administration—A Report of Thirteen Cases." The number of leucocytes in the blood was found to constantly increase, but the increase appeared to bear no relation to age, sex, character of the disease, extent or seat of exudate, or administration of antitoxin. Neither was much change found in the proportions of the several varieties of leucocytes. It did appear, however, as though there was a relative diminution in the number of eosinophiles. Dr. George Foster presented on invitation a communication entitled, "A Study of the Hemopoietic Organs in Diphtheria and Tuberculosis." In a considerable number of observations, including studies of the thymus, spleen, and palpable lymphatic glands, a constant increase in the eosinophile leucocytes was found in the organs named, such as was not present in the bodies of children and others dead from contagious diseases observed at the Municipal Hospital. The reaction is, therefore, considered specific to the toxins of diphtheria and tuberculosis and of the nature of a defensive response.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Tennessee State Board of Medical Examiners,

May 1-2, 1907.

MATERIA MEDICA.

1. Name two emetics, antipyretics (other than the coal-tar derivatives), antithelmintics, emmenagogues, diuretics, arterial sedatives, giving the dose of each, and the indications for the use of each.
2. What are antiseptics (internal)? Name two. Give the dose of each and the best mode of administering them.
3. What preparation of veratrum viride would you use? In what pathological lesions and in what dose would you administer?
4. Name one alkaloid each of cinchona, belladonna, jaborandi, hyoscyamus, opium, and hydrastis. Give the dose of each and indications for use.
5. What is the physiological action of podophyllin?
6. How would you prepare a normal salt solution and under what conditions would you use it?
7. How is Fowler's solution prepared?
8. How is the tincture of iodine prepared?

ANATOMY.

1. Name the muscles of the face and of the forearm.
2. Name the bones of the face and of the wrist.
3. Describe the external carotid artery, point of origin, and general course.
4. Describe the femoral artery. Give the point of origin and the important branches given off in its course.
5. Describe the diaphragm, its openings, the different organs in contact with or separated by it.
6. Describe the scrotum.
7. Name the largest muscle in the human body. Give origin and insertion.
8. Name the ligaments of the shoulder and elbow joints.

CHEMISTRY.

1. (a) What is a urinometer? Of what does it consist? How graduated? (b) With what is urine compared? What is needed for an ordinary uranalysis? (c) If upon boiling urine you get a cloudy precipitate, how would you determine the nature of the precipitate?
2. (a) State methods of obtaining urinary sediments. (b) What is a centrifuge and how is it used?
3. Tell what you know about oxygen. (Do not write more than one page.)
4. The stomach of a person supposed to have been poisoned with arsenic is brought to you; give in detail

your method of determining the presence or absence of that poison.

5. Give symptoms of strychnine poisoning and treatment of same. Differentiate its symptoms from those of other convulsive disorders. In case of death from strychnine poisoning, why is it more difficult to prove than arsenical poisoning?

6. Heat. (a) Define and explain expansion, conduction, and transmission. (b) What changes of state are produced by heat? (c) What is specific heat? (d) Give sources of heat.

7. State how, and the methods employed, and the source from which iodine is obtained. Common medicinal preparations used? How used? Doses and effects?

8. Define: (a) Static electricity. (b) Dynamic electricity. State uses of each. Define terms volt, ohm, and ampere.

SURGERY.

1. Define the terms "Science" and "Art" of surgery. What is aseptic surgery? What is antiseptic surgery? Illustrate the two latter.

2. Describe a Pott's fracture. How caused? Give treatment for (a) simple, (b) compound, (c) comminuted Pott's fracture. (d) Describe a Colles' fracture and give treatment. (e) What is a common result of almost any fracture of a long bone?

3. Diagnose fecal impaction from invagination of a gut, and give method of treating the first.

4. What is osteomyelitis? Diagnose. Give causation and treatment.

5. Give diagnosis and treatment of cancer of the breast.

6. Define perineorraphy and trachelorraphy, and describe the operation for each.

7. Describe in detail a curettement of the uterus.

8. Define (a) prostatectomy, (b) cystotomy, (c) nephrectomy, (d) nephrotomy, (e) lithotomy. Give in detail your method of enucleating an eye.

PRACTICE.

1. Do you expect to have any puerperal fever in your practice? If you do, what will be the cause? Define puerperal fever, and give treatment.

2. Give symptoms, diagnosis, prognosis, and treatment of acute Bright's disease. Should you have uremic convulsions, what would be the cause, and how would you treat them?

3. What do you understand by gallstones? What is the technical name. Give diagnosis and treatment.

4. Give diagnosis and treatment of hereditary syphilis.

5. (a) Write a prescription for general debility, (b) one for an acute bronchial cough, (c) one for chronic constipation, (d) one for chronic diarrhea.

6. Define acute rheumatic fever. Give symptoms and treatment. What is the most frequent complication?

7. Give symptoms, diagnosis, prognosis and treatment of enterocolitis.

8. Give symptoms, prognosis, and treatment of purpura hœmorrhagica.

PATHOLOGY.

1. What is the meaning of active, and what of passive pathological changes?

2. What pathological changes take place in the kidneys during an attack of acute congestion?

3. What pathological changes take place in the kidneys during an attack of acute nephritis?

4. What pathological changes take place in the liver during an attack of acute catarrhal jaundice?

5. What pathological changes take place in catarrhal pneumonia?

6. Give pathology of diphtheria.

7. What pathological changes take place in the spleen during an attack of malarial fever?

8. What is the pathology of erysipelas?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

TENNESSEE STATE BOARD OF MEDICAL EXAMINERS,

May 1-2, 1907.

MATERIA MEDICA.

1. *Two emetics*: Apomorphine hydrochloride, dose gr. 1-10 (hypodermically); Antimony and potassium tartrate, dose gr. j.

Two antipyretics: Quinine sulphate, dose gr. v.; Tincture of aconite, dose ♏x.

Two anthelmintics: Oleoresina Aspidii, dose gr. xxx.; Pelletierine tannate, dose gr. x.

Two emmenagogues: Pill of aloes and iron, dose 2 pills; Black oxide of Manganese, dose gr. ij.

Two diuretics: Infusion of Digitalis, dose ʒij; Sparteine Sulphate, dose gr. ij.

Two arterial sedatives: Tincture of Aconite, dose ♏x; Tincture of Veratrum, dose ♏xv.

2. *Internal antiseptics* are drugs which, when swallowed or inhaled are supposed either to destroy or inhibit the growth of microorganisms.

Two internal antiseptics: Creosote, dose ♏iij; best administered in the form of an emulsion with codliver oil. Betanaphthol, dose gr. iv; best administered in keratin-coated pills if its action is desired on the intestines.

3. The preparation of veratrum viride to be used, is the tincture; dose ♏xv.

4.

	One alkaloid.	Dose.
Cinchona	Quinine	gr. iv (of the Sulphate)
Belladonna	Atropine	gr. 1/150 (of the Sulphate)
Jaborandi	Pilocarpine	gr. 1/5 (of the Hydrochloride)
Hyoscyamus	Hyoscine	gr. 1/150 (of the Hydrobromide)
Opium	Morphine	gr. 1/4 (of the Sulphate)
Hydrastis	Hydrastine	gr. ss (of the Hydrochloride)

5. *The physiological action of podophyllin*: It is a gastrointestinal irritant; it has a drastic and cholagogue purgative action.

6. Normal salt solution is prepared by adding six drachms of sterilized sodium chloride to a liter of distilled water in a sterilized glass flask.

It is used to irrigate fresh wounds, to remove blood or foreign bodies, for cleansing mucous or serous surfaces; it also is used for intravenous injection when the circulation is failing; by hypodermoclysis it is used also when the circulation is rapidly failing, and after profuse hemorrhage, in cases of shock, septicemia, and uremia.

7. Fowler's solution is prepared by boiling ten grams of arsenic trioxide, twenty grams of potassium bicarbonate, and thirty grams of compound tincture of lavender in sufficient distilled water to make one liter.

8. Tincture of iodine is prepared by dissolving seventy grams of iodine and fifty grams of potassium iodide in alcohol enough to make one liter.

CHEMISTRY.

1. (*a*) A *Urinometer* is a form of hydrometer, used for determining the specific gravity of the urine.

It consists of a cylinder and a spindle.

The graduation on a urinometer is so constructed that the spindle sinks to the zero point when it is immersed in water at a given temperature. The denser the fluid into which the spindle is immersed, the higher it rises. The ordinary urinometer is graduated from 0 or 1,000 to 60 or 1,060.

(*b*) Urine is compared (for purposes of specific gravity) with distilled water at a certain temperature which is indicated for each instrument (generally 60° F.).

For an ordinary urinalysis, there are needed: A graduated cylinder in which to measure the quantity of urine; litmus paper; a "color scale"; urinometer; test-tubes, test-tube holder, test-tube stand; ureometer; albuminimeter; burette; pipettes; glass funnel; beakers; filter papers; alcohol lamp; centrifuge; slides and cover slips; stains; microscope; nitric acid; Fehling's solution; hypobromite solution, for ureometer; acetic acid; sodium hydroxide solution, potassium hydroxide solution.

(*c*) The cloudy precipitate may be due to urates, phosphates, or albumin. If it is due to phosphates, it will clear upon the addition of a few drops of nitric acid; if it is due to urates, it will disappear on being heated.

2. (*a*) Urinary sediments may be obtained (1) by allowing the urine to stand; (2) by centrifuging.

(*b*) A centrifuge is an apparatus by means of which the solids in a fluid are separated by centrifugal force.

4. "The stomach should first be carefully examined as to its pathological condition, and also for the presence of solid particles of the poison. It should then be cut up into small fragments with scissors known to be perfectly clean, and, together with its contents, placed in a clean porcelain evaporating dish; distilled water added in sufficient quantity, together with about one-sixth the bulk of pure hydrochloric acid, and heated gently for about an hour, when most of the solid portions will have become disintegrated. After cooling, the mixture is thrown upon a muslin strainer and the solid matters washed several times with pure water and squeezed. The strainer and contents should be preserved for subsequent examination. The filtrate should be concentrated by evaporation over a water-bath and then filtered through paper." (Reese.)

After this, the Reinsch test can be applied, as follows:

To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

5. The *symptoms of strychnine poisoning* are as follows: "Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours.

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

Tetanus is the principal condition from which strychnine poisoning is to be differentiated. In *tetanus*, the onset is gradual, is apt to begin with trismus, swallowing is difficult or impossible, the condition is persistent, consciousness is dulled or lost, and there is history of a wound or injury. In *strychnine poisoning*, the onset is more sudden, the muscles of the jaw and neck are generally the last to be affected, there are marked remissions with muscular relaxation, consciousness is retained, and there is no history of a wound or injury.

Strychnine poisoning is more difficult to prove than arsenic poisoning, because in the latter the poison is not decomposed, and in spite of any chemical change the element arsenic remains, and may be demonstrated. This would not be possible in the case of strychnine.

6. (*a*) As a rule, all bodies *expand* when heated, and diminish in volume on losing heat.

Conduction of heat is its transmission from one molecule to the neighboring molecule.

Transmission of heat may take place by conduction, convection, and radiation.

(*b*) By heat, substances can be converted from the solid state to the liquid state, and from the liquid to the gaseous state, as ice can be converted by heat to water, and then to steam.

(*c*) *Specific heat* is the amount of heat required to raise the temperature of a substance a given number of degrees.

(*d*) *Sources of heat,* are: The sun, the interior of the earth, friction, pressure, electricity, chemical action, combustion.

7. Iodine is obtained from sea-weed. Sea-weed is burnt, and the ashes (called kelp) are extracted with water and the solution is then evaporated. The mother liquor is then distilled with manganese dioxide and sulphuric acid, or the iodine is obtained by passing chlorine in, and heating.

The common medicinal preparations, with doses, are: Tincture of iodine, ♏ij; Lugol's solution, ♏ij; potassium iodide, gr. vij; sodium iodide, gr. vij; ammonium iodide, gr. iv.

8. (*a*) *Static electricity* is electricity at rest; and is usually produced by friction.

(*b*) *Dynamic electricity* is electricity in motion; it is also called current electricity.

A *volt* is that electromotive force, which, acting steadily through a conductor having a resistance of one ohm, will produce a current of one ampère.

An *ohm* is the amount of resistance shown by a column of mercury 106.3 centimeters long with a base of one millimeter square, at O°C.

An *ampère* is such a current of electricity as would be given with an electromotive force of one volt through a wire with the resistance of one ohm.

SURGERY.

1. In *Aseptic Surgery* everything that is to come in contact with the wound is previously made free from germs, and all possibility of infecting the wound is avoided.

In *Antiseptic Surgery* antiseptic solutions are used to kill the bacteria that may be present or that may enter during the course of the operation.

2. *Pott's fracture* consists of a fracture of the lower end of the fibula, about three inches above the tip of the malleolus; and a fracture of the internal malleolus. The foot is twisted outward, the sole everted, and the heel drawn up; there is a depression at the site of the fracture, the inner malleolus either projects prominently or the fragment can be felt and crepitus elicited; the foot is shortened, and the ankle is swollen and widened.

Pott's fracture is usually caused by twisting the foot.

Colles' fracture is a fracture of the lower end of the radius; it is generally transverse, and is usually within an inch or an inch and a half of the articular surface. There is a characteristic deformity caused by the lower fragment and the carpus forming a prominence on the dorsal surface; at the same time there is a projection on the palmar surface just above the wrist, caused by the upper fragment. The hand is abducted and pronated, and the styloid process of the ulna becomes very prominent.

A common result of almost any fracture of a long bone, is shortening of the limb.

3. In *fecal impaction*, there is a history of long continued and increasing constipation, feeling of languor and depression, anorexia; the abdomen becomes distended gradually, and the symptoms develop slowly; pain comes on gradually, and later becomes continuous; there is usually a tumor in sigmoid flexure or cecum, it is doughy and firm; constipation is absolute.

In *invagination of the intestine*, there is a sudden onset, with severe pain which later tends to subside; rarely constipation, but often diarrhea may be present, accompanied with tenesmus; there is apt to be marked prostration or collapse; a movable tumor can often be felt in line of the colon, or in the rectum; in extreme case the invagination may protrude from the anus.

Method of treating fecal impaction: "The best means of relief are afforded by copious enemata of warm water administered in the knee-and-elbow position. Continuous irrigation by the siphon syringe is very efficacious, and, if employed for half an hour at a time, the hardest mass softens and gradually becomes disintegrated. The stream of water should be directed against the obstructing mass by means of a rectal tube. Before enemata are commenced it is often advisable to inject a few ounces of olive oil. Some physicians recommend copious injections of sweet oil with spirits of turpentine in the proportion of one drachm to the pint of oil. Metallic mercury has been strongly advocated. Occasionally, when low down, the fecal mass may be removed by scoop or spoon." (From *Reference Handbook of the Medical Sciences.*)

4. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone.

It is *caused* by infection, the bacteria gaining entrance either through a wound, or by extension from neighboring tissues, or they may be brought by the blood.

It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint and not *near* it. (2) *Tubercular arthritis*, in which the onset is slow, and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis*, in which the bone and periosteum are not affected, and in which there is always a wound.

In *osteomyelitis*, the *treatment* consists in relieving the constitutional symptoms, and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution, and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

6. *Perineorrhaphy* is the operation of suturing a lacerated perineum.

Trachelorrhaphy is the operation of suturing a lacerated cervix uteri.

8. (*a*) *Prostatectomy* is the operation of removing the prostate gland, entirely or in part.

(*b*) *Cystotomy* is the operation of making an incision into the urinary bladder.

(*c*) *Nephrectomy* is the operation of removing a kidney.

(*d*) *Nephrotomy* is the operation of making an incision into the kidney.

(*e*) *Lithotomy* is the operation of removing a calculus by cutting into the urinary bladder.

Enucleation of the eyeball is performed as follows: "A general anesthetic is generally given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the conjunctiva, we may begin with a tenotomy

of the internal rectus and then divide the conjunctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward, and thus the optic nerve is put on the stretch. A pair of enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn, slightly opened, and the nerve is divided close to the sclera. The eyeball is held between the thumb and index finger of the left hand, and the oblique muscles and other unsevered attachments are divided. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is usually closed with a single suture, which is passed through its edge at intervals and tied like the string of a pouch. The eye is bandaged and the patient kept in bed for a day." (May, *Diseases of the Eye.*)

PRACTICE.

1. I don't expect to have any puerperal fever in my practice, due to any want of care on my part.

The *causes of puerperal fever* are: Pathogenic bacteria which may be introduced into the woman in several ways, such as by the hands of the physician, nurse, midwife, or of the patient herself; by unclean instruments and catheters; by coitus during the time immediately preceding labor; by contact with secretions from wounds of any kind, no matter where situated; by general unhygienic surroundings, and contact with a patient suffering from scarlet fever or erysipelas on the part of any one attending on the woman. The percentage of such cases will depend on the care exercised by doctor, nurse, etc.; when infection does occur, it is generally streptococcic infection, either pure or mixed with other germs.

Puerperal Fever is a fever beginning within a week after labor, attended with acute inflammation of the reproductive organs, and with septic infection of the blood and general system.

3. *Gallstones* are calculi formed in or found in the gallbladder or bile ducts.

The technical name is *Cholelithiasis.*

The *diagnosis is made* by (1) the intense and sudden pain, radiating from the right hypochondriac region to the right shoulder. (2) Cold sweat, feeble pulse, vomiting, and collapse may be present. (3) Chill and fever are present at the onset. (4) The calculus may be found in the feces.

Treatment. Prophylaxis includes: Plain and easily digested food, the ingestion of plenty of good drinking water between meals, sufficient outdoor exercise, salines, and the avoidance of indigestion.

During an attack: Inhalation of chloroform, a hypodermic of morphine (gr. 1/4) and atropine (gr. 1/120), application of heat, and diffusible stimulants if shock is present.

Cholecystotomy may be performed, and the stones removed.

5. (*a*) For *General Debility*:

℞. Strychninæ sulphatis, gr. j.
Quininæ sulphatis, ʒj.
Tincturæ ferri chloridi, ʒiij.
Acidi phosphorici diluti, ʒv.
Glycerini q.s. ad ℥v. Misce.

Signa: One teaspoonful after each meal.

(*b*) For *Acute Bronchial Cough*:

℞. Ammonii carbonatis, gr. xxxij.
Fl. extr. senegæ.
Fl. extr. scillæ, āā ʒj.
Tincturæ opii camphoratæ, ʒvj.
Aquæ destillatæ, ʒiv.
Syrupi Tolutani q.s. ad ℥iv. Misce.

Signa: One teaspoonful every three hours.

(*c*) For *Chronic Constipation*:

℞. Fl. extr. cascaræ sagradæ, ℥ss.
Tincturæ nucis vomicæ, ʒv.
Tincturæ belladonnæ, ʒij.
Glycerini q.s. ad ℥ij. Misce.

Signa: One teaspoonful three times a day.

(*d*) For *Chronic Diarrhea*:

℞. Morphinæ sulphatis, gr. j.
Bismuthi subnitratis, ʒj. Misce.
Et fiat in chart. no. xij.

Signa: Take one powder three or four times a day.

PATHOLOGY.

1. By *active pathological change* is understood that condition in which formation exceeds waste, and growth results. Examples: Hypertrophy, Tumor-formation, Regeneration.

By *passive pathological change*, is understood that condition in which morbid processes are attended by arrest or impairment of nutrition. Examples: Atrophy, Degenerations, Infiltrations, Necrosis.

7. In malaria, the spleen is much enlarged, and is of a brownish color, with areas of deep pigmentation; the capsule is thickened.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.
Alabama*	W. H. Sanders, Montgomery	Montgomery
Arizona*	Ancil Martin, Phoenix	Phoenix July 6
Arkansas*	F. T. Murphy, Brinkley	Little Rock July 14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco August 4
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver July 7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven July 14
Delaware	J. H. Wilson, Dover	Dover June 16
Dist. of Col'bia	Geo. C. Ober, Washington	Washington July 14
Florida*	J. D. Fernandez, Jacksonville	Ocala July 13
Georgia	E. R. Anthony, Griffin	Atlanta May 4
Idaho	W. F. Howard, Pocatello	Boise October 6
Illinois	J. A. Egan, Springfield	East St. Louis May —
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis May 26
Iowa	Louis A. Thomas, Des Moines	Des Moines June —
Kansas	D. P. Cook, Clay Center	Kansas City June 9
Kentucky*	J. N. McCormack, Bowling Green	Louisville July 7
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans May 21
Maine	Wm. J. Maybury, Saco	Augusta July 7
Maryland	J. McP. Scott, Hagerstown	Baltimore June 9
Massachusetts*	E. B. Harvey, State House, Boston	Boston May 12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Detroit June 9
Minnesota	W. S. Fullerton, St. Paul	St. Paul June 2
Mississippi	J. F. Hunter, Jackson	Jackson May 12
Missouri	J. A. B. Adcock, Warrensburg	Kansas City May 14
Montana*	Wm. C. Riddell, Helena	Helena October 6
Nebraska	E. J. C. Sward, Oakland	Lincoln May —
Nevada	S. L. Lee, Carson City	Carson City May 4
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord July 15
New Jersey	J. W. Bennett, Long Branch	Trenton June 16
New Mexico	J. A. Massie, Santa Fe	Santa Fe
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo May 19
N. Carolina*	G. T. Sikes, Grissom	Winston, Salem May 21
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks July 7
Ohio	Geo. H. Matson, Columbus	Columbus June 9
Oklahoma*	J. C. Mahr, Shawnee	Shawnee
Oregon	B. E. Miller, Portland	Portland July 7
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg June —
Rhode Island	G. T. Swarts, Providence	Providence July 2
S. Carolina	W. M. Lester, Columbia	Columbia June 9
S. Dakota	H. E. McNutt, Aberdeen	Deadwood July 8
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville May 5
Texas	G. B. Foscue, Waco	Waco June 16
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City July 6
Vermont	W. Scott Nay, Underhill	Burlington July 14
Virginia	R. S. Martin, Stuart	Richmond June 24
Washington*	C. W. Sharples, Seattle	Seattle July 7
W. Virginia	H. A. Barbee, Point Pleasant	Charleston July 14
Wisconsin	J. V. Stevens, Jefferson	Madison July 14
Wyoming	S. B. Miller, Laramie	Cheyenne June 10

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Oklahoma.—All physicians desiring to practise medicine in this State must have been actively engaged in the practice of medicine, and been legally licensed to do so, in either Oklahoma or Indian Territory prior to and on November 16, 1907. Those who cannot comply with the above, must take the examination. There is no reciprocity.

Virginia.—At the December meeting it was agreed to reciprocate with Maine. At the examination held in December, applicants with licenses from the following States were granted certificates without examination:—Maryland, West Virginia, District of Columbia, and Pennsylvania.

Texas has established reciprocity with the Medical Boards of Maine, Maryland, Missouri, and Nebraska. Some doubt has been raised as to the constitutionality of the new medical practice act in this State. The ground for this is the section requiring reregistration, which is declared to be unconstitutional because retroactive and tending to impair vested rights.

Missouri.—By the new medical practice act of this State, applicants for the State Board Medical Examinations must have a diploma from a reputable medical college requiring a four years' course, and also a high school certificate or its equivalent; this latter must have been granted before beginning the study of medicine.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

OUTLINES OF PSYCHIATRY. By WILLIAM A. WHITE, M.D. 12mo, 232 pages, paper, $2. The Journal of Nervous and Mental Disease Publishing Company, New York.

PROCEEDINGS OF THE ROYAL SOCIETY OF MEDICINE. Large 8vo, paper, illustrated; price, 7 shillings and 6 pence. Longmans, Green & Co., London.

L'AEROBISATION DES MICROBES ANAEROBIES. By GEORGES ROSENTHAL. Large 8vo, 105 pages, illustrated, paper; price, 5 francs. Felix Alcan, editeur, Paris.

DIE AUGENHEILKUNDE IN DER ROMERZEIT. By Dr. RODOLFO DEL CASTILLO, Quartiellers in Madrid. 8vo, 137 pages, illustrated, paper. Franz Deuticke, Leipzig und Wein.

APPLIED PHYSIOLOGY. By FREDERICK A. RHODES, M.D. 8vo, 206 pages, muslin. Medical Press, Pittsburg.

TREATISE ON HYGIENE. By R. H. FIRTH. 4to, 993 pages, muslin, illustrated. P. Blakiston's Son & Co., Philadelphia.

SURGERY. By W. W. KEEN, M.D., LL.D. 8vo, 1,132 pages, illustrated, half morocco, $8 net. W. B. Saunders Company, Philadelphia.

ATLAS DER GYNÄKOLOGISCHEN CYSTOSKOPIE. By Prof. Dr. W. STOECKEL. 4to, illustrated. August Hirschwald, Berlin, N. W.

A SHORT PRACTICE OF AURAL SURGERY. By J. ARNOLD JONES, M.B., Ch.B. (Vict.), F.R.C.S. (Ed.). 12mo, 264 pages, muslin, illustrated, $1.50 net. John Lane Company, New York.

COSMETIC SURGERY. By CHARLES C. MILLER. 16mo, 135 pages, muslin, illustrated, $1.50. Published by the author.

MALADIES DES OS. Par P. MAUCLAIRE. Large 8vo, 316 pages, paper, illustrated. J. B. Baillière & Fils.

MATERNITY. By HENRY D. FRY, M.D., Sc.D. 12mo, 220 pages, cloth $1.50. The Neale Publishing Company, New York.

CONSIDERATIONS HISTORIQUES SUR LA BLENNORRHAGIE. Par le Dr. ERNEST ROUCAYROL. Large 8vo, 244 pages, paper, illustrated. S. Steinheil, Paris.

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. 8vo, 453 pages, illustrated, paper. Hartford, Conn.

ALIMENTATION ET HYGIENE DES ENFANTS. Par le Dr. JULES COMBY. 12mo, 531 pages, illustrated, paper. J. Rueff, Editeur, Paris.

ETUDES SUR LA PHYSIO-THYROIDE. Par les Drs. LEOPOLD LEVI et HENRI DE ROTHSCHILD. Large 8vo, 363 pages, illustrated, paper. Octave Doin, Editeur, Paris.

PRIMITIVE SECRET SOCIETIES. By HUTTON WEBSTER, Ph.D. 8vo, 227 pages, muslin, $2 net. The Macmillan Company, New York.

DISEASES OF THE HEART. By Prof. TH. V. JÜRGENSEN, Prof. L. V. SCHROTTER, Prof. L. KREHL. Large 8vo, 848 pages, illustrated, half morocco, $5 net. W. B. Saunders Co., Philadelphia.

THE PROLONGATION OF LIFE. By ELIE METCHNIKOFF. 8vo, 343 pages, illustrated, cloth. G. P. Putnam's Sons, New York.

MODERN ELECTROTHERAPEUTICS. By FREDERICK STRONG, M.D. 8vo, 112 pages, muslin, illustrated, cloth. Rebman Company, New York.

LEITFADEN ZUR KLINISCHEN UNTERSUCHUNG DES BLUTES von Dr. med. C. S. ENGEL, 8vo. 170 pages, illustrated, paper, 5 mark. Verlag von August Hirschwald, Berlin.

VORLESUNGEN UBER DIÄTBEHANDLUNG INNERER KRANKHEITEN, von Professor Dr. H. STRAUSS. 4to, 340 pages, paper. Verlag von S. Karger, Berlin.

GESCHICHTE DER LARYNGOLOGIE IN WÜRTZBURG, von Professor Dr. OTTO SEIFERT. 4to, 68 pages, paper, 3.50 M. Curt Kabitzsch (A. Stubers Verlag), Berlin.

UBER DEN EINFLUSS DER GESCHLECHTSFUNKTIONEN AUF DIE WEIBLICHE KRIMINALITÄT. von Dr. JUR. SEIGFRIED WEINBERG. 8vo, 34 pages, paper. Carl Marhold Verlags Buchlandlung, Berlin.

BERICHT UEBER DEN XIV. INTERNATIONALEN KONGRESS FUR HYGIENE UND DEMOGRAPHIE. Professor Dr. NIETNER. 8vo, 314 pages, illustrated, paper. Verlag von August Hirschwald, Berlin.

PERSONAL HYGIENE IN TROPICAL AND SEMI-TROPICAL COUNTRIES. By ISAAC W. BREWER, M.D. 12mo, 130 pages, cloth, illustrated, $1.00 net. F. A. Davis Company, Philadelphia.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 18, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	444	189
Diphtheria	436	51
Measles	1640	46
Scarlet Fever	1005	66
Smallpox	2	—
Varicella	108	—
Typhoid Fever	19	5
Whooping Cough	13	3
Cerebrospinal Meningitis	7	7
Malarial Fever	—	—
Totals	3674	367

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending April 17, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Alabama, Huntsville, vicinity	January–April	50	..
California, Los Angeles	Mar. 21–28	7	1
San Francisco	Mar. 21–28	15	..

THE CANCER PROBLEM.*

BY EUGENE COLEMAN SAVIDGE, M.D.,

NEW YORK.

"It must be confessed that in spite of the time, brains, energy, and money which have been expended during the past few years in the attempt to solve the problem of cancer in almost all parts of the civilized world, little or no apparent progress has been made."—Editorial, MEDICAL RECORD, June 29, 1907.

The present writer is as orthodox as any member of this society regarding the prompt operation for surely recognized malignant disease. He is not alone, however, in asking whether life is really prolonged by surgery in some cases, notably in malignant diseases of the uterus. Nevertheless, the majority of the profession at present, for the lack of better resource, advise prompt operation. But, because such provisional attitude is apt to grow into a habit during the years when we are losing our plasticity, is just why we should keep additionally alert to other possibilities,—while not wavering in the best we have.

When your Chairman drafted me for this paper it was my intention to present you the sifting from a wide range of reading. I have not found time to do this; instead, I shall try to ask some questions which will bring out your experience in the discussion.

This society will probably agree as follows regarding the state popularly known as cancer. (The subdivisions will litter and obscure our discussion):

1. The quotation heading this paper has accurately stated our present relation to the problem of cancer.

2. That researches as to cancer cause based on bacteriological transmission—to go into detail—have yielded no result. Therefore nothing can be expected from either antiseptic or antitoxin treatment.

3. That even if the theory of wandering cell from embryonal life were capable of proof, such proof would give us nothing of value in treatment. We could never penetrate fetal life and anchor the displaced or wandering cell.

4. That though surgery has done thoroughly clean work, at least in uterine cases, it has been followed with prompt recurrence and speedy death.

If this society does so agree it must necessarily hold that our present resource, while the best we have, is unsatisfactory; and that our position, while not abandoning our best and time-honored resource, is one of "hopeful expectation."

Notwithstanding the foregoing statements, the writer believes there are signs of promise important enough to merit studied consideration. We have an indication of the cancer cause. We have a sane hope, confirmatory of this indication, regarding the successful treatment of cancer. This indication, which becomes more conclusive the more we study it, lies in the physical variation in the isomeric quality of the most primitive elements entering into the composition of protoplasm. (The isomers, let us refresh our minds, are "substances having the same centesimal composition, but whose molecules have essentially different structure and chemical properties.")

The trail of our search, therefore, leads directly to the subtle mystery why elemental carbon exists as coal and as diamond; or why certain substances are, under varying conditions, dextrorotary and levorotary—diverting the rays in one quality to the right, in another, to the left—when submitted to polarized light.

The hope of successful cure lies in the restoration, or the preservation, of certain ferments the secretions containing which seem to be altered, or abolished, long before the human organism reaches the state of cancer. As the ptyalin of the saliva, for example, mysteriously changes starch into dextrin and sugar in a manner similar to the mysterious transformation of the isomers from right to left rotary quality, and *vice versa*, from one side of the polariscope to the other, this application of ferments to changed isomeric quality is an exact dovetailing between theory of cause and hope of cure. It may be added that it is not based upon so simple a procedure as the application of trypsin to the local manifestation of cancer. The writer doubts if the cancer problem will ever be solved by the application of a juice to a spot: or even the hypodermatic application of a ferment to the organism.

Without entering too deeply upon the great work on fermentation by Pasteur—beginning about 1860, passing through the crucible of indifference if not ridicule, but now fully entered into the warp and woof of medical knowledge—let us consider in outline its connection with cancer.

Pasteur discovered the dimorphism of the double tartrate crystal. One isomer in solution is dextrorotary in the spectroscope; the other is levorotary. That is, one of these varieties of the same thing turns the polarized light to the right, the other turns it to the left. As a laboratory test, to separate these two diverging forms of the same thing, they were subjected to certain fermentative tests. *The yeast plant ferment was found to act on the left isomer, while the ferment of the mold acted upon the right solution.* Please stick a pin in this fact; it has a vital bearing on what follows. The left-hand isomer, susceptible to the yeast ferment, is indifferent to the mold ferment; and the right-hand isomer, susceptible to the mold, is unacted upon by the yeast plant.

Another important point accented by Pasteur was the difference between the same thing—to use an apparent Hibernianism—according to its derivation. The difference between laboratory pro-

*Read at a meeting of the Section on Obstetrics and Gynecology of the New York Academy of Medicine, March 26, 1908.

ducts and the same substances derived from organic compounds was this: the natural organic products rotate the polarized light either to the right or left according to quality,—but always one way, to the exclusion of the other isomer. Or, as Duclaux, quoted by Beard, says: "Nature alone knows how to manufacture one isomer without making the other."

So much for the "asymmetry of the carbon atom and the nitrogen pentavalent atom,"—to quote the resonant technique. Now, Beard, building upon Pasteur's work, or independently of it, has discovered an analogous asymmetry in the organic as well as in the inorganic world. In certain fish and amphibians, he has found the existence of "two distinct and separate nervous systems in their life history,—the transient nervous system functioning for a time, then suddenly begins to fade away in slow degeneration."

This analogy in the organic world may be simply significant; it may not mean that cosmic laws act on the elemental compounds of the ganglionic protoplasm sufficiently to divert the rotatory quality; as, for example, the irritation of a nerve center has produced glycosuria. On the other hand, it may mean more. As the embryological development of the human individual passes from the simple cell all the way up the line, distinctly through the fish-life analogy (remember, surgery is sometimes necessary to close the branchial clefts remaining open after birth, as evidence of the time in the evolution of the fetus when it had gills like a fish)—so might it be within the same range of possibility that there is a similar asymmetry of the nervous system in fetal life as that found in certain fish by Beard. But this would prove too much for the present writer's exposition; it would throw part of the causation back into fetal life, and except as explaining fetal or adolescent cancers, would help us no more for practical curative purposes than the wandering cell theory of Conheim. I prefer to cite it as an analogy, that it may not disturb the brighter hope.

This asymmetry both in the organic and the inorganic compounds, like that of the two nervous systems, in the words of Beard, "is based upon the fundamental verity of the asymmetry of the carbon atom."

Now, if the carbon atom were symmetrical, and carbon existed only as diamond, we would freeze to death in winter. So with our food stuff. If the carbon atom should suddenly become symmetrical, existing only in its left-hand isomer while our digestive ferments attack only the right-hand isomer, or *vice versa*, we would likewise starve to death. With warehouses full of levoalbumins, levocarbohydrates, famine would still stalk the land, because our digestive ferments could no more change them into assimilable substance than they now can the granite of the mountains.

Further, and of transcending importance to life,—for without the fact there would be no life,—this very powerlessness of our digestive ferments to act upon the levoalbumins of the human body is perhaps the basal reason why the human stomach does not digest its own walls. Otherwise, like the anaconda engaged in swallowing his own tail, at the conclusion of each complete digestive act the individual would disappear in a cloud of his own dust and vapor.

Isomeric integrity may be the life principle; it is certainly the life principle which prevents self-digestion, as any stomach in condition would digest another stomach if put therein,—as we eat tripe, for example. In fact, this is Herbert Spencer's theory of nerve force: that "in nervous action the disturbance transmitted is a wave of isomeric change." In other words, our molecules vibrate from right to left, or the reverse, to produce nerve action. Should they stay wrongly right, or wrongly left, or stop altogether, it is not hard to presume disaster.

To assail isomeric integrity, therefore, may be to entail sectional death; and cancer undoubtedly is this.

The importance of the ferments of the body,—called here digestive, and including the opsonins of the blood,—is becoming daily clearer to the profession. They are the elements of assimilation, the agents of protection. Yet daily we have to explain to the laity that, when the secretions are locked up by fever,—when the ferments are not being secreted,—putting food requiring digestion into the alimentary canal is just like hiding meat particles between the teeth. There being no ferments to prepare it for assimilation, it carries with itself and gathers from about it, elements for its own decay. It is a toxin instead of a nutrition. Plus secretion it is friend; minus secretion, it is foe and poison.

But recently even further importance has been shown in the ferments. The opsonins in the blood are still acquaintances almost too new for men outside of laboratories to discuss. Yet we are sufficiently established in our knowledge to say that certain ferments in the blood make the germ palatable to the phagocyte, thereby assisting these latter to digest specific infections in the blood. We can talk about the opsonic index in furunculosis, in tuberculosis, in syphilis; we can almost definitely state that for each infection an opsonin ferment exists in the blood, which when in condition protects the organism by making that specific germ palatable to the blood scavengers—thereby assisting in the destruction of the infection. We even pretend to say that when the opsonic index for tuberculosis is below normal the patient *has* tuberculosis, even though no bacilus may yet be found. We are even injecting our products into the blood to irritate or stimulate the opsonins for the specific malady we wish to conquer.

I am able at this point to report a perfectly well authenticated opsonin cure of malignant tertiary syphilis of the most extreme type. A miner, afflicted with ignored syphilis, untreated until its malignancy crippled him, was stricken with smallpox. His employer, one of my own patients, himself having had smallpox, charitably nursed this double leper through the scourge. Recovery from smallpox left him permanently cured of his tertiary syphilis. The explanation then was that the smallpox germ had killed the great pox germ. The explanation is now simpler. The stimulation of the opsonins by the acute infection brought a collateral stimulation of the opsonins of syphilis, and this ferment caused the cure of the man of a disease incurable in him at that time by drugs. Whether this was an accidental collateral stimulation of opsonins, or a direct stimulation, we do not know. But suppose we had always available a less objectionable but equally swift and efficient method, would not humanity greatly profit?

Please, therefore, let us revivify in our consciousness the absolute necessity of the ferments in making food really food to us,—selecting our bread from stone for us by practically the same process that Pasteur used in his laboratory years ago.

With sure selective instinct, keener than the scent

of the bloodhound, as imperious as the call of an acid for its base, these our agents of assimilation and protection stand at the portal of our being, and decide: this is right deflecting, this is left deflecting; this is bread, this is stone—saying to one, "Go ye into tissue"; and to the other, "Get you hence!"

Let us also make vivid to ourselves this conception of the protective and curative powers contained in these newly-discovered ferments in our blood. *All this is in vital relation with the cancer problem.*

In a paper read before the New York Obstetrical Society in 1903, the present writer said: "Women have lacerations, retained secundines, ectopics, fibroids, and cancers. And we operate on them brilliantly, with this or that technique, on whose minor details we spend much time in discussion. But in all these things—*I am not sure that I will except even the malignant troubles*—we get behind the outward symptom and arrive at first causes when we 'get them together' in the tubular system, as we clinch our fist, or contract our body when expecting a blow. We thus symbolize the great passion of the universe—the movement from circumference to center—'the love of a ton of lead for the center of the earth.'"

This reference to the malignant troubles was more than literary fervor. I had long pondered over the fact that cancer was locally but an exaggeration of normal cell tissue, as seen by the microscope. As the isomers may be defined as "the difference between the same thing," so cancer may be called an isomer of normal tissue.

Then, certain distinctly noted antecedents of cancer had forced themselves upon my attention in my opening professional days, when abundant clinical material was at hand. In most of the cancers I saw, the appearance of the patient suggested the diagnosis. Is this not a common experience with others? The local examination usually only confirms what we knew before we make it. When, then, did the pallor, the significant loss of weight, the distinctive physiognomy—the cancer family resemblance—begin with relation to the malignancy? This was my first self-questioning.

The diminution, or absence of the free hydrochloric acid in the gastric juice in cancer of the stomach was the next insistent point. Did this appear before the cancer? Had it any relation to the cancer cause? Or was it the result of malignancy, and why?

What caused the marked increase in saliva noticeable in cancer patients? The saliva has its ferment. Was this increase simply more water poured out in the struggle of the organism to bring up its supply of ptyalin?—just as we have more urine in advanced Bright's, in the effort of the organism to get out in this way the diminishing proportion of solid constituents. Or was it an actual increase in ferment production in the saliva? And did it precede cancer; or did cancer precede it?

What, too, had the thryoid gland to do with it? Why was the thyroid altered in cancer, and did the change precede the malignancy or come with it? We all know what subtle influence the thyroid gland, when given by mouth, has on the organism—how obesity melts away and the individual disappears fractionally from the landscape. Perhaps, like the fleeing obesity, it is the malignancy that is kept on the run by a vigilant thyroid in healthy individuals. Perhaps, in whole or in part, it is the slowly changing thyroid which allows the installation of the malignancy in the others: who knows?

Has this change in the thyroid any connection with the significant loss of weight? If we can accomplish this result with thyroid taken from an animal and administered by mouth, could not the thyroid within the individual by perversion cause this undue reduction in weight? If we saw in a patient with suspected malignancy a slowly gaining weight would we not give it a second consideration?

Graves' disease with its glandular—and hence ferment—relations, has always seemed to me to be a preparatory stage of cancer—the cure either averting the cancer, or the severity of the preparatory stage killing the patient before the culmination is reached.

Just as the spleen is charged with certain obscure relations to pernicious anemia and leucocythemia—as grave as cancer—so may the spleen, pancreas, as well as the ductless and intestinal glands, be said to bear an equal relation to the malignancy of cancer.

Indeed, noting the frequency of sarcomatous growths in the bone marrow in pernicious anemia, who can say whether a given case may not have been first a bone-marrow cancer, or even a blood-cell cancer before it became pernicious anemia? If this is not the order, the reverse order is equally convincing. For if pernicious anemia prepared for cancer, this proves a step in the march toward cancer—for the arrest of which there is certainly hope.

I have elsewhere cited a significant seeming relation between ferment secretion and another disease,—presenting an analogy with the present discussion. If adrenalin released into the blood causes the arterial tension observable long before the ensuing Bright's disease is shown in the urine, may there not be a relation between this release of adrenalin and the suppressing of the selective action of the ovaries, as seen in patients after double ovariotomy? Testicular inactivity, in presenility of the other sex, has also seemed to show the same relation to arterial tension long before urinalysis shows a reason in the kidney.

Let us, therefore, not lose the vivid realization that all these glandular activities have to do with the ferments upon whose integrity depends our life. It is a sane hope that such glands, showing incipient failure, can be restored to full integrity.

That we do know a force that will cure some cancers and cause some cancers I believe will be denied by no man in the profession. This is one thing known. A second thing known is the action of this force upon the ferments. We have thus two known links in the chain.

With the mighty uplifting of the veil during the last decade few more important hidden things have been revealed than *x*-ray and radium. The exact relation of these two rays to each other, to the sun, and to polarized light, we do not know. May we call these occult powers of light, cosmic, telluric, or radial? This much at least we know: the sun, the *x*-ray, and the radium ray—this occult radical force—both cure and cause diseases, and each acts significantly upon the ferments.

The solar action upon fermentation is embodied in the proverbs of all the languages: "Where the sun comes the doctor shuns; mold is found on the shady side, etc." But this, like many of our other half-truth complacencies, will need readjustment.

Briefly, this "radial" force can cause disease: Blonds can not live in the tropics; they lack a curtain of pigment to shield their blood cells. Qui-

nine has been found to have opalescent qualities which rob the plasmodium of light required for its existence. Hence, this quinine-bestowed curtain to the blood cell containing the plasmodium, explains backwards and forwards why quinine is good and sunlight bad for malaria. (Remembering what has already been said about pernicious anemia, why may not this anemia with its blood cells uncurtained by hemoglobin allow too great a radial action from the sun upon the protective epsonic ferments, and if only by their destruction and no more direct action, aid in the mysterious change in isomeric quality?) Recall the burns caused by the *x*-ray; the inhibiting action on the procreative glands, etc. In the *Annals of Surgery*, November, 1907, is a thorough study of the increasing list of *x*-ray carcinomata. See also Osler's "Modern Medicine," Vol. I, pages 63 and 64, for data regarding gangrene and cancer from *x*-rays, as well as injuries following exposure to radium.

With equal brevity let us look at the side of cures from the occult radial forces. There are apparently more cures than hurts.

In the *Berliner klinische Wochenschrift*, April 1, 1907, Widmer reports the cure of a carcinoma by repeated exposure to the direct rays of the sun. Radiotherapy has been employed with success in pernicious anemia by Grego of Geneva. (I ask again, how can we know it was not marrow cancer?) The *x*-rays have also been used with success in similar conditions by Beaujard of Paris. (*Semaine Médical*, Nov. 17, 1907, page 202.)

Dr. Robert Abbe, in the MEDICAL RECORD of October 12, 1907, presents an extended paper on the subject of cures by radium and its influence on animal and bacterial life. For example, dry seed exposed to radium has its growth retarded after planting, according to the time of exposure. In animal life, meal worms are repressed in their life history cycle by radium, while their brothers and sisters, "unradiumized," complete several cycles as beetles, eggs, meal worms, etc. So likewise is bacterial life checked or destroyed.

This radial action—of sun and ray and ray—is probably in the direction of a cure when it acts repressively on the noxious bacterial (or ferment) life. It is probably acting in the direction of hurt when it destroys our assimilative and protective ferments.

Our conception does not require that it act directly as a changer of isomeric quality—though it probably can do this as easily as the sun draws pigment—for it is easy to see how it reaches the same result indirectly when it destroys the ferments which would otherwise digest the noxious isomer.

Proven beyond all cavil, however, is the existence of this occult force which brings both hurt and cure. We know that it acts on the ferments; we know that ferments destroy one isomer and allow the other to remain untouched; we know then that it thus acts at least once removed on isomers.

We know what the force does, pro and con; but we have not yet succeeded in bridling it so that it will always act pro and never con. This may be our next success when we have learned its relation to isomeric integrity.

But that one known force can thus act pro and con presupposes that other forces may so act.

This march of antecedents, in cancer has formed an intensely interesting chapter in my line of special study. For fifteen years I have been cautiously insinuating under the notice of the profession discussion of many minor and detached matters, that the thus printed word might be used in presenting an entirely new system of approach in medicine. This I have called "Synthetical Medicine," and have published in the MEDICAL RECORD, April 7, 1906.

Synthetical Medicine, the science of the unclassified, "assumes to recognize and postpone that eventual trouble, be it in heart, liver, kidney, or blood-vessel, which a grouping and study of present conditions will often show years before it takes place in its text-book form; . . . it asks, what trouble in addition to the text-book classification, has the patient?"

The profession has not understood this, nor considered it very important, nor shown much interest; but I cite it here to show the formed mental habit which brought this march of antecedents in cancer under my notice.

The extent of my debt in this special subject of cancer to the suggestions of Beard and Bell is apparent. But the conception herein differs widely from that held by either.

If the asymmetry of the carbon atom causes one form of the same thing to assume a right rotary quality and another form a left rotary to the polarized light; if one of these quailties is assimilable under our digestive ferments, is acted upon by our protective ferments, and the other is not; if the cell proliferation of cancer is simply an exaggeration of normal cell proliferation,—either of opposite isomeric quality, hence insusceptible to our ferments: or of the same quality, and undisciplined by our ferments because impaired—then, whatever deflects our protoplasm from one isomer to its opposite, or impairs the quality of our protective ferments, may be said to be the cause of cancer, long before its local manifestation. And whatever deflects this malign isomer to its benign opposite, or whatever restores the integrity of the failing ferments,—long before the local manifestation—may be said to be the cure for cancer.

If the radial forces—the sun and ray and ray—even if not acting directly upon the carbon atom in our protoplasm, act repressively on our protective ferments, thereby allowing the wrong isomer to flourish into exaggerated cell life like the rank foliage of the tropics, then the "radial" forces may be said to cause such a cancer.

If pigment absorption, hair graying, hemoglobin disappearance, allow the radial forces to attack the cancer opsonin among the thus uncurtained blood-cells, then here is a more remote cause of cancer.

Conversely, if we can shield our protective ferments from the destructive radial forces, and at the same time expose our noxious elements thereto, the radial forces may be said to cure such cancers.

If a perverted thyroid, withdrawn from its mysterious guardianship against wrong isomers, leaves them to flourish like weeds in the absence of the gardener, while the recreant gland disrobes the skeleton of flesh, then perverted thyroid is another cause of cancer. And conversely, the restoration of such a thyroid is the cure for cancer so produced.

But whether one item, or all, whatever restores glandular activity, replaces the disturbed ferment protection, restores the isomeric integrity,—that item, or aggregate of items, thereby cures the cancer.

The incipient cause, the study of the march of antecedents, the application of the cures, all lie in the domain of Synthetical Medicine.

The use of trypsin for the cure of *developed* cancer as Beard says, "fits like a key in the lock" with the theory outlined above. Beard's idea is not its local application, but the overwhelming the sys-

tem with it hypodermically. Many careful men are trying this and I believe a fair view of their conclusion is that trypsin does not cure the cancer.

That trypsin may fail even in most developed cases would not nullify the importance of its testimony if it succeeds in any. For if it has any power over the local manifestation of cancer—aside from a certain digestive action such as pineapple juice might have on thickened mucus in the throat,—it proves that the excessive cell proliferation by being susceptible to the ferment, contains a carbon atom of that isomeric quality acted upon by that ferment—and not of the opposite quality. This is as sure a test as our test for albumin and sugar. Here, then, is light; here is differentiation; here is invitation along a new line of research.

For while medical humanity may prefer a sign, a specific, a single "distinctly defined" process of application, we must not hope always to have given us such a definite entity as we received in the antitoxin for diphtheria, for example. It is doubtful whether we shall ever be able to apply a juice to a spot, merely, and cure a cancer. Nor can we hope to secure a single injectable curative juice. How simple this would be for the man who had the juice! The very theory of the complex causes of cancer is against this hope. But if we can increase the opsonin ferments, stimulate a phagocytosis, and thus make a man's blood corpuscles eat up his own cancer; or if we can stop the change in the thyroid, the alteration of the saliva, the gastric, pancreatic, and intestinal juices, the ominous loss of weight, the ghastly robbery of the hemoglobin curtain for the cells of the blood, there may still be additional help from the injectable juice, or from the local juice at the local spot. But the source is more important than the local manifestation.

This conception of making an element in a man's blood eat up his own disease, though hardly born to the medical profession, probably points the line of our future march. But to use this new possibility we must see things earlier than we are wont under our present methods, which teach us to see only the accomplished fact and blind us to the widely scattered preliminary stages. It is only when these are finally focused that they realize our textbook descriptions.

For example, though all medical men may not agree, I firmly believe that the more skilful among us can foretell the advent of tuberculosis long before the bacillus gives any sign of its presence. A rougher, cruder diagnostician, who must have his hectic, cavity, and bacillus, before he can see the tuberculosis, naturally is limited to short range procedure. He is more of a prognostician than a diagnostician. He can foresee death more clearly than cure. His resources are climate, overfeeding, and creosote,—frequently helpful; but far removed from what might have been done had the earlier picture been seen—the falling opsonic index, the wasting muscles, the depleted vitality, the unfair nutritive division,—the bulk of the nutrition going to the brightly burning nervous system, with the lower forms of tissue slowly starving, as the sappers and miners prepare the soil for the seed. *We should infer the harvest when we see the plow.* This is Synthetical Medicine.

If cancer, therefore, is the climax of a synthetical progression, finally showing itself locally, we may be able to avert it when so understood and so attacked. Perhaps this has been done.

I would not dare report seriously to this Academy what I honestly half-believe: that these beginning changes have been seen and have been purposefully attacked, and the cancer has been averted. But this is a fair report: Patients with all the preliminaries have been restored to health. But of course there is no proof that cancer (uterine, is the special reference), would ever have culminated.

But this, too, is a fair report: If any man hereafter sees a patient with these detailed preliminaries of cancer state—long before the patient has the disease classified in our text-books—and does not purposefully wipe offending item after item off the slate, such a man is not protecting his patient as he should.

To accentuate the relation of the general condition to cancer, let me continue from the quotation begun at the head of this paper:

"There are five distinct groups of malignant tumors, and Mr. Sutton draws attention to the fact that in dealing with these tumors, the position is such that we are unable to point to any absolute histological indication of malignancy, *and that clinical and histological characters must be considered together.* Microscopic examination, even when conducted by the most expert microscopist, can not determine with precise certainty whether a tumor is malignant or not. 'The true character of such tumors can only be determined by careful observation of the patient.'"

Dr. Robert A. Murray, before the New York Obstetrical Society, November 12, 1907, quoted authorities on this same fact. Many cases of fibroids show precisely the same microscopy as cancer.

Prof. James Ewing, at the last meeting of this section, February 6, 1908, quoted authorities who characterize chorioepithelioma as varying so much in significance that at one extremity it is criminal to operate because it is so benign as to recover sometimes spontaneously; while at the other extremity it is criminal to operate because it is so malignant that the end is hastened by operation.

These facts are vitally significant. The same microscopic slide, therefore, which, plus history of unimpaired general condition, would bring a benign verdict, becomes cancer when pinned to the history of cachexia. *The cachexia is the cancer,* therefore. For a broken down and infected fibroid, like an infected leg, is only a surgical problem of infection and suppuration, or of gangrene from compression—it has no relation to the general problem of impaired ferments, isomeric integrity, plus a local malignancy.

"An ounce of prevention is worth a pound of cure," and "keeping in good condition," as a basis of this theory is as fatuous a conception as would be futile the efforts of the man lazily adopting it. On the contrary, it implies direct, purposeful attack upon a start toward a definite and fatal end: it is by no means a good-natured, tolerant, passive state of ordinary hygiene.

Human limitation implies that we rarely see or hear the obscure upon which we have not had our attention concentrated. Our experience, as embodied in the answers to the following questions, may therefore be no experience at all, unless we have specially directed our attention to the points involved. I respectfully solicit the wisdom of the profession upon the following points:

1. Who have seen cancer develop in patients that have been under observation, say a year before the cancer became unmistakable?

2. What has been the relation observed between the cancer and the cachexia? What observations have been made of the various secretions? When did the glands begin to fail; when did the weight loss begin? etc.

3. This question is preceded with an avowal that no desire exists to discredit surgical methods. Restricting the question to uterine cases, what is the honest conviction of those with the experience regarding the quick and possibly more virulent return of the malignancy after operation? (Perhaps those who operate most frequently are the least qualified to say how long life might have lasted without an operation, as they do not know this side. The excellence of their equipment in one direction is the measure of their limitation in the other.) Yet the strictest estimate is necessary on this point, for if there is anything in the new trend, surgery may be the worst thing to do to a cancer. Like the potato which would grow but one plant as a whole, subdivided grows a plant for each eye—like cell segmentation, like sowing parts each capable of reproducing the whole—cutting may be simply spreading elsewhere the local manifestation.

Quite on the other hand, if it be true that the only nonrecurrences of cancer after surgery are found with those who were operated upon before the advent of cachexia, *then the new trend all the more imperatively demands even prompter surgery.*

Starting, therefore, with the frank admission that nothing as yet has been accomplished; still clinging to our best procedure of surgery, is there not reason to consider this sequence with scientific openness of mind?

A certain known, but not understood, "radial" force can act upon products containing the asymmetrical carbon atom to change their isomeric quality as shown by polarized light. That one force can so act presupposes that other forces may so act.

The natural ferments contained in the secretions of the body, digestive and protective, "digest" one series of isomers and leave the opposite series untouched. Therefore, the action of this occult "radial" force—this assailing of isomeric integrity,—can change protoplasm from digestibility to indigestibility to the natural ferments, and *vice versa.*

The local cancer product consists presumably of changed isomers allowed to grow instead of being "digested." This is made all the more probable by the disappearance of the opsonic ferments in the blood in all such diseases as have been subjected to controlled observation; and, specifically in cancer, by the gradual suppression of the enumerated ferments. These ferments—presumably—begin to modify long before transition from the preliminary to the final state called cancer. Therefore, even if there be no change in isomeric quality, the secretion suppression would explain the growth of the cancer weed cells that effective ferments would have removed.

If there be no flaw in these significances, the cure for cancer as well as its prevention, lies in the realm of Synthetical Medicine, to which the attention of the profession is again respectfully directed.

If the foregoing seems as radical as some of my earlier papers, I beg that you will pardon this almost unpardonable reminder:

Ten years ago before this Academy, alone in the profession so far as I know, I had the temerity to say regarding overzealous abdominal operations almost precisely what Dr. Boldt, at our last section meeting, outlined to you in reviewing "the recent advances in gynecology."

The adverse reception first given this presentation, and the cordial welcome greeting it ten years later, are alike matters of record.—both gratifying and instructive.

66 West Fiftieth Street.

THE EFFECTS OF URBAN CONGESTION ON ITALIAN WOMEN AND CHILDREN.*

By ANTONIO STELLA, M.D.,

NEW YORK

In dealing with the effects of urban congestion on Italian women and children in America, it is impossible not to begin a little farther back than the title of this paper implies, and consider first what degree of congestion exists among them and to what extent overcrowding prevails in certain Italian quarters.

Every one is familiar with the unhygienic and overcrowded condition of the dwellings of Italians in the large cities of the United States. It is a well-known fact that they reside in the poorest quarters and in the slums, so-called, not because they like to be there, but because their poverty compels them to live there. They have nothing, in fact, in common with the slum population proper, nor do they bring or contribute any of the degrading characteristics of the professional vagrant or tramp which we meet among the "people of the abyss." They live there because many times also their work is there. So in New York we find them on the streets adjacent to the Bowery, Mulberry Bend, "the Lung Block," old "Richmond Hill," "Little Italy," or way up in the Bronx. In Boston we find them in the "North End" and in the neighborhood of Hanover Square. In Chicago they occupy chiefly the Nineteenth District, South Clark street, Dearborn street and West Madison; in New Orleans, "Little Palermo" and the old French Quarter, and so on in Philadelphia, Buffalo, Denver, and elsewhere.

Without here repeating the results of the more general inquiries made in that connection by the Tenement House Department of New York, the South End House of Boston, the "Octavia Hill Association" of Philadelphia, Hull House and the City Homes Association of Chicago, and others which every one may consult, I will simply quote a few recent data gathered by myself and by the Committee on Congestion of Population, with the assistance of the Italian government, whose interest and generosity towards its expatriates stands unparalleled in the history of emigration. They will give you an approximate idea of the almost incredible conditions in which the greater part of our people live in New York.

Two typical Italian blocks have been investigated by this Committee, besides 174 families scattered throughout the lower part of Manhattan, and some two hundred houses visited by myself in the last two years on account of the occurrence of tuberculosis, or other diseases, which brought them to my attention. The first block investigated is the one in Harlem bounded by East 112th street, East 113th street, First avenue, and Second avenue; the second block is the one down town bounded by East Houston, Prince, Mott, and Elizabeth streets. The results of this investigation have been shown at the Exhibit (of Congestion of Population) by statistics, photographs, and diagrams. I shall not relate here in detail all the valuable information gained from this house-to-house inquiry, but shall mention only a few of the salient points which have a direct bearing on our subject, and from them you can draw your own conclusions.

*Read at the Conference on Congestion of Population, held at the Museum of Natural History in New York on March 10, 1908.

Of the families examined, 18 per cent. occupied one room, and 34.4 per cent. only two rooms, showing a condition much worse than the average on the East Side, where a family consists of seven persons living in three rooms, three members being at home, two at school, and two at work. In the "Barracks," as that portion of Elizabeth street between Houston and Prince is known to the police, less than three out of every hundred families had five rooms, and yet, as if one and two rooms for a family were overabundant, about one-third of the families had one lodger, 41 per cent. two lodgers, 16.5 per cent. three lodgers, and 3.1 per cent. four lodgers. Thus, counting two children under twelve as equivalent to one adult, one-sixth of the rooms in this block were found to be housing as many as four adults each.

In the same block the great majority of the families are paying over 25 per cent. of their income in rent, and some families over 50 per cent.; in most cases the number of cubic feet of air for the occupants of sleeping rooms was less than is provided in hospitals and prisons, and the mixing of sexes in sleeping rooms, though not common, was discovered in a number of cases. (In one case five men and seven women were found sleeping in three rooms, though it was impossible to judge how they slept.)

Out of the 174 families investigated in scattered portions of Manhattan, only seventy-one were not overcrowded. The rest had from two adults and one child per room up to five adults regularly occupying the rooms. Of this number, there were thirty-two one-room apartments, sixty two-room apartments, fifty-one three-room apartments, twenty-six four-room apartments, and five five-room apartments. One hundred and thirty-five had lodgers, some of them as many as five and six. The moral condition can better be imagined than described.

The results of my own investigation in some other parts of the city were just as startling. On Third avenue, near Twenty-sixth street, a family of eleven—four adults and seven children—and three clerks were living in a dark middle room, and a large, bare, rear room, an average of seven people to the room. In the section of the Bronx, bounded by East 148th and East 153d streets, Morris, Cortlandt, and Park avenues, I found some of the very worst conditions. In a rag shop on Morris avenue there were no less than eighteen people, men and women, working, eating, and sometimes sleeping, and in one double, new-law tenement in this district I found 1,100 people, divided in 130 apartments, not counting all the night lodgers.

Justice demands that I should say at once, in this connection, that there is an enormous difference between the various Italians, and while those of the North seem to have a higher sense of personal dignity in the selection of their homes, the immigrants of the South, especially the peasants from Sicily, Calabria, Basilicata, and Abruzzo, without exception, live in the most overcrowded and unsanitary condition.

How can health be preserved under such circumstances? When we stop to consider that nine-tenths of the Italian immigrants arriving in the United States come from rural districts, and less than one-fourth settle in the country, the large majority (77.2 per cent.) of them crowding the large cities, the evils of urban congestion attending on this rural exodus cannot be too strongly emphasized. For, while we are all agreed that urban life lowers the physical standard of the people and is detrimental to the national physique, few of us are aware that this injury is more profoundly and more extensively felt by the robust peasants, than by the thin and pale city dwellers.

Whether it is that the abrupt transition from rural to city life does not give the nomad people, so to speak, accustomed to an outdoor existence, time to prepare and elaborate sufficient means of protection against or adjustment to the new environment—special enzymes or opsonins, or we do not know what, that all animals and even plants develop when transferred to a new environment; or whether it is that the very high tension to which the nervous system is subjected by city life, often accused as a factor of disease, is in reality the mainspring of that hyperacuteness and overactivity of all our functions, which braces the system constantly to a higher degree of vigor and vitality—it is certain that death and diseases are more prevalent among the rural people settled in cities, than among the city people themselves, in spite of the more robust appearance of the former. The example of the Indians, of the Negroes, of many savage people, and presently of the Italians in America, furnishes an irrefutable proof of this fact.*

We have no extensive data for New York like those gathered by Körösi for Budapest and Vienna, comparing the death rate and the overcrowding per room, but it will be interesting to quote here a statistical table arranged on this basis for the inhabitants of Lausanne by Prof. Niceforo,† the results of which would surely apply just as forcibly to New York.

Rent of Twenty-five Apartments in Lausanne expressed in Francs	Death Rate for 1,000 Living	Cubic Meters of Air Space available for Each Lodger on the Total Number of Rooms
250	34.6	26.1
293	26.7	26.4
328	14.6	30.5
345	23.7	34.3
353	19.6	34.4
380	21.6	30.2
384	17.2	30.4
401	20.5	31.8
414	15.7	39.5
418	22.0	36.5
419	23.4	32.5
442	23.0	30.0
476	15.1	33.6
517	18.8	45.4
673	11.4	45.2
680	13.0	52.2
717	27.0	29.8
800	23.4	60.6
819	13.1	59.5
856	15.4	53.7
900	11.5	60.7
1,016	14.6	66.2
1,192	13.9	64.9
1,392	10.0	59.6
1,490	11.8	84.4

The intimate relation that exists between the quantity and quality of air respirable for each individual and the amount of diseases and number of deaths resulting therefrom, is too evident and has been too exhaustively studied by hygienists to need repetition. Lagneau has shown, from statistics collected from 662 cities in France, that the denser the population the greater is the number of deaths from tuberculosis. "Thus, while the death-rate per 1,000 of the population from this cause, in cities of 5,000 inhabitants, was 1.81, in cities of

*I called attention to this apparent paradox two years ago in a paper I read at the Congress of Tuberculosis in Milan, noting the prevalence of consumption in New York among the contadini of Sicily and Basilicata, in preference to the former citizens of Naples and Palermo, and I have seen with satisfaction the same views confirmed since. (Dr. Norburne Jenkins, MEDICAL RECORD, February, 1908; M. de Fleury, etc.)

† Les Classes Pauvres.

10,000 inhabitants it was 2.16, in cities of 20,000 inhabitants it was 2.71, in cities of 30,000 inhabitants it was 2.88, in cities of 100,000 it was 3.05, in cities of 450,000 it was 3.63, and in Paris, with upwards of three million inhabitants, the death-rate per 1,000 of the population rose to 4.90." From the Report of the Health of Towns Commission for Great Britain it appears that the ratio of phthisis and other similar diseases in Dundee, Scotland, increases with the overcrowding in dwellings. "Taking the ratio of dwellings of four rooms and upwards as 10, it was found that the other ratios were: For three rooms, 17; for two rooms, 20, and for one room, 23. The same thing has been observed in London. According to the Annual Report of the Medical Officer of Health in London, 1898, in districts with under 10 per cent. of overcrowding (overcrowding being taken to mean where more than two persons occupied a room in tenements of less than five rooms) the death-rate per 1,000 living from tuberculosis is 1.10; in districts with under 15 per cent. overcrowding it is 1.43, in districts with under 20 per cent. overcrowding it is 1.61, in districts with under 25 per cent. overcrowding it is 1.80, in districts with under 30 per cent. overcrowding it is 2.07, in districts with under 35 per cent. overcrowding it is 2.42, and in districts with over 35 per cent. overcrowding the death-rate per 100 living from consumption is 2.63. Similar observations conducted for the four years previous to 1898 showed the same obvious relation between the amount of overcrowding and the phthisis death-rate."*

The tables arranged by Dr. Herman Biggs, of the New York Health Department, are very illuminating on this point, and must be reported in full here:†

PHTHISIS.

DEATH RATES PER 1,000 LIVING, 1894–1898, INCLUSIVE.

Proportion of Total Population Living More than Two in a Room (in Tenements of Less than Five Rooms)	Death Rates per 1,000 Living				
	1894	1895	1896	1897	1898
Districts with under 10 per cent....	1.07	1.18	1.07	1.14	1.10
" " 10 to 15 " "	1.38	1.49	1.46	1.42	1.43
" " 15 to 20 " "	1.57	1.64	1.61	1.63	1.61
" " 20 to 25 " "	1.58	1.83	1.67	1.75	1.80
" " 25 to 30 " "	1.81	2.09	2.06	2.10	2.07
" " 30 to 35 " "	2.11	2.42	2.13	2.32	2.42
" " over 35 " "	2.46	2.66	2.55	2.64	2.63

This table shows an obvious relation between the amount of overcrowding and the phthisis death-rate.

PHTHISIS.

DEATH RATES PER 1,000 LIVING, 1898.

Proportion of Total Population Living (in Tenements of Less than 5 Rooms) More than Two in a Room	0	5	20	25	35	45	55 and Upwards
Dists. with under 10%....	0.23	0.39	1.19	1.50	1.94	2.05	1.77
" " 10 to 15 "	0.39	0.34	1.44	2.13	3.09	2.68	1.91
" " 15 to 20 "	0.62	0.30	1.05	2.01	3.41	3.43	2.36
" " 20 to 25 "	0.57	0.37	1.59	2.39	3.66	4.01	2.78
" " 25 to 30 "	0.78	0.33	1.57	2.58	4.16	4.58	3.04
" " 30 to 35 "	0.81	0.49	2.00	3.00	5.58	6.26	3.26
" " over 35 "	0.85	0.50	1.82	3.25	6.04	6.12	4.41

It will be noted from these tables that in the most overcrowded districts the mortality from phthisis is more than three times that obtaining in the least crowded territories.

The death rate and the rate of morbidity give the best measure of the effect of urban congestion on the health of the people. We shall consider separately the death rate and morbidity of Italian children first, then the death rate and morbidity of the women.

MORTALITY OF ITALIAN CHILDREN.

Through the courtesy extended by the President of the New York Health Department and the interest taken by Dr. Guilfoy, the Registrar of Vital Statistics, who has personally supervised the search and compilation of the figures here submitted—and to whom I wish to acknowledge publicly my indebtedness—I am able to present here to-day some very interesting data of the death rate of Italians in certain blocks of New York, classified by age and specified diseases. (It is the first time that this has been done by age-group for any nationality in Manhattan, and the results are extremely instructive and illuminating, in that we are brought face to face with the domestic and social conditions of the people studied in the same quarters at the present moment, the detailed investigation of which, omitted here for the sake of brevity, illustrates most forcibly the effects of overcrowding.)

The ten blocks suggested for the study of the death rate (see following table for details) were selected among others in the city because they contained a large number of tenement houses of the old and new law style, and were chiefly inhabited by Italians or people living under similar conditions to theirs. The comparison with the latter has proven most surprising, for while in certain blocks in the Italian quarter there is a very high death rate, in certain other blocks, half a mile away, in the Jewish quarter, the death rate is only one-half as great as the average death rate of the city, "yet in the latter district there is a greater population, the tenement houses are taller, and the general sanitary conditions are worse."

This once more illustrates the influence of the ethical factor in racial resistance to disease, which in turn—as in the case of the Jews—is due, less to religious restrictions, than to a certain immunity against the ills of urban life, acquired through long residence in cities.

According to those figures, we find, as you will see, by glancing at the appended table, that while the general death rate for the city of New York in 1905-06 for all ages was 18.35, and under five years was 51.5, in some of the various Italian blocks* here examined, was respectively:

BLOCK	FOR ALL AGES	UNDER FIVE YEARS
A	24.5	87.03
B	24.9	92.2
C	22.4	81.6
D	22.57	74.7
E	22.3	83.12
F	23.2	59.5

The death rate for 1905-06 for the entire city, and for those under five years in the Italian blocks, was as follows:

FOR ACUTE RESPIRATORY DISEASES	FOR DIARRHEAL DISEASES	FOR DIPHTHERIA
City death rate, 12.7	City death rate, 12.9	City death rate, 2.80
Italian Blocks	*Italian Blocks*	*Italian Blocks*
A.....32.9	A.....22.3	A.....4.34
B.....47.8	B.....19.1	B.....3.71
C.....35.3	C.....17.6	C.....4.61
D.....28.6	D.....13.8	D.....8.93
E.....49	E.....19.3	E.....3.20
F.....17.9	F.....14.9	

*For the sake of brevity we shall call block A, B, C, D, E, F, respectively, the following Italian blocks:

Block A—East 112th, East 113th, First and Second Avenues.
Block B—Mott, Prince, Elizabeth, East Houston.
Block C—East 114th, East 115th, First and Second Avenues.
Block D—East 108th, East 109th, First and Second Avenues.
Block E—East 106th, East 107th, First and Second Avenues.
Block F—Jones Street, Cornelia, West 4th and Bleecker.

*The Tenement House Problem, deForest and Veiller.
†Dr. H. Biggs: The Relation of Tenement Houses to Tuberculosis, *loc. cit.* Vol. I.

Dr. Guilfoy had already called attention to the disastrous effects of urban congestion on the health of Italians, and to the "cosmopolitan character of the New York population increasing the city death rate." If we compare the more recent data arranged by age-groups with his previous figures, we come to the same conclusion. This is what he had to say on the subject: "Under the rates from bronchopneumonia the most surprising rate of the whole table appears, the rate among Italian children reaching the enormous height of 710 per 100,000, more than two and a half times higher than that of American children. When we consider under what conditions the Italian families herd together, and the opportunities this affords for the spread of contagious and infectious diseases, the difficulties encountered by the sanitary officers can be imagined but not described. Think of seven tenement houses with a population of 1,500 of a square block that by actual count harbors 5,100 souls, surrounded by other blocks harboring an average of 2,000, and you obtain an idea of the necessity for eternal vigilance on the part of the health officials."

Further on he says: "The lobarpneumonia column reiterates the story as to the Italian national predisposition to disease of the respiratory tract; here the Italian leads, with none of the others a close second. In the typhoid fever column, omitting rates whereof the number of deaths do not reach twenty, the Italians and Austro-Hungarians have the highest mortality; under the heading *measles*, we notice that the Italian children have a *mortality of almost five times* that of the entire city, the Italian children show the highest mortality from *scarlet fever* and *whooping cough*, with the Hebrew children a close second. The mortality from diarrheal diseases among them is double that of the Austro-Hungarian, and treble that of the average for the entire city." (MEDICAL RECORD, January 5, 1908.)

In the presence of such startling figures, we cannot fail to notice at once the deleterious effect of city life and overcrowding on the appalling mortality of Italian children; the preeminence of this factor is seen at a glance, when we notice that the greatest number of deaths is given by the infectious diseases, which are those most influenced by agglomeration, while the organic diseases (affections of the heart, kidney, etc.) show a very low percentage among Italians compared with other nationalities. (See the accompanying table prepared by Dr. Guilfoy and reprinted from the MEDICAL RECORD of January 25, 1908.)

The excessive death rate from acute respiratory diseases must be directly charged to overcrowding in the rooms and lack of proper ventilation during the course of the illness, rather than to atmospheric changes, as commonly believed. Modern investigation on the etiology of the diseases of this group has established without question that the exciting factor is a microorganism which requires such conditions for its growth and multiplication, as are usually found only in the living body. The infection, when it occurs, "must always be the result of communication directly or indirectly from one human being to another. The conclusion, therefore, seems to be justifiable that these diseases are essentially communicable." (Report of the Medical Committee for the Investigation of Acute Respiratory Diseases of the Department of Health of the City of New York, Part I, 1905.)

Diarrheal diseases bear also an intimate relation to "urbanization," and statistics all over the world prove that infant mortality from this cause is higher in the cities than in the country, and more so in the densely-populated districts of the same city than in the better quarters. Indeed, so marked is this difference, that Dr. Robertson, in an investigation made in Manchester, Eng., found that 98½ per cent. of the deaths from diarrhea had occurred in houses of five rooms or under, and only 1½ per cent. in houses of over five rooms."*

But the death rate is only one of the exponents of the effect of urban life on the health of the children. A study of their morbidity adds corroborative evidence to the one already furnished.

MORBIDITY OF ITALIAN CHILDREN.

It is very difficult to measure in exact figures the effects of overcrowding on the morbidity rate. We all know that it is considerable and most detrimental to the health of children, but we cannot produce the technical proof thereof, nor can we separate the many other elements (heredity, underfeeding, etc.) that are potent factors in the production of disease.

In the case of the Italian children, however—due exception being made of extreme cases of poverty, congenital defects, or child-labor for which we have tried to account in the present investigation—we are as nearly correct as one can be, when we assume that *the lack of fresh air and the congestion of bedrooms*, as it exists in the tenement houses of New York, are at the base of all their ills. The testimony given before the Interdepartmental Commission of England gave a new emphasis to this point, and it was amply proven that "the bad physic of the urban population is due to the deprivation of fresh air, which comes to be the distinguishing factor of physical deterioration." (Par. 4865-4871.) The birth rate, which is very high among the Italians of the first generation, must also be taken into account in explaining their high infant morbidity and mortality.

A. The percentage of Italian children suffering from rickets is exceedingly high (75 to 80 per cent.), in spite of the fact that many of them (65 per cent.) are breast-fed. Rhachitis is not a mere deformity of bones, but is the expression of profound pathological changes occurring in practically all the tissues of the body.

Due allowance being made for the defective composition of the mother's milk—which, in my opinion, is the principal factor of the prevalence of the disease, and which in turn reverts on urban congestion that diminishes the stamina of the mothers—overcrowding and bad housing in general seem to be the primary causative agent, even above the dietetic factor, which in the case of the Italians would appear to play only a secondary part. In fact, the Italian children brought up in rural districts are as badly fed, if not worse, than the children of the city, yet there is an immense difference in their physique. "Rickets is an unknown disease in Hammonton," writes R. J. Mead, referring to the Italian children of that community, "and there is no indication of anemia."† The prevalence of rickets is, in my opinion, the most potent factor back of the high mortality of bronchopneumonia of the Italian children in New York.

B. When we compare the general appearance and resistance of Italian children brought up in the healthful environment of the country and those in the city, more important differences are noted,

and if we compare their average height and weight, as in the table here appended, we find an advantage of almost one inch and a half more in height and one pound more in weight for the childdren of the rural districts. Here is a table giving the average height and weight of Italian children in Turin, New York, and Hammonton, by sex and age. (Dr. Holt, "The Care and Feeding of Children," Meade, *loc. cit.*)

AVERAGE HEIGHT AND WEIGHT OF ITALIAN CHILDREN IN TURIN, NEW YORK AND HAMMONTON, BY SEX AND AGE.

C. *Malnutrition* and *anemia, scrofula, adenoids,* and *poor dentition* are next to rickets, or concomitant with it, the most frequent pathological conditions met with among the children of the New York tenements. That they are the direct result of bad housing, and not heredity, is proven by the fact that almost all Italian infants are born strong and healthy, and their weight is often above the average even when their mothers look pale and sickly, and live in the poorest districts. This fact, besides, seems to be true of all poor classes, according to the evidence furnished by eminent obstetricians before the British Interdepartmental Commission (Dr. Alfred Reichholz, Dr. Malins, etc.)

Dr. Holt says that "one of the most striking things about children suffering from malnutrition is their *vulnerability.*" They "take" everything, and have but little resistance to the common infectious diseases of childhood. This applies most forcibly to the Italian children in New York, whom we see fall victims of one disease after another, and frequently sick for almost an entire season.

D. Had we been allowed to inspect this year's records of the physical examination of school children—for instance, in the public schools Nos. 21, 23, 8, or 172, all situated in thickly-populated Italian districts, I would now be able to tell you what proportion the Italian children contribute to the 70 per cent. of foreign born who are found suffering from one or another physical defects. But since this has not been possible—we hope the superintendent of the public schools will allow it some other time—permit me to extend the term child to the age of puberty, or a little above that, say twenty years, so as to include those whom we call the second generation of Italians. I shall then be able to furnish you with very interesting information

regarding the poor physique of Italian boys in New York in relation to congestion.

I refer here to the data furnished by the physical examination of the Italian recruits at the Consul's office. Every year a great number of young men are examined in New York and in various consular agencies for military services. The number of rejections is very great, many times double and treble the ones in Italy. In 1906 11,396 young men of twenty or thereabouts were examined; 3,921 of them were rejected, and 7,475 were accepted, subject to reexamination in Italy.* In the years past a still higher percentage of rejections prevailed.†

Among the commonest causes of rejection are anemia and debility of the constitution, which implies no special disease, but just poor muscular development, insufficient height, defective chest expansion, and sometimes latent tuberculosis.

E. As to the prevalence of tuberculosis among the second generation of Italians, suffice it to say that it is most prevalent in all its forms, and while the pulmonary manifestations are seen most frequently above the fifteenth year of age, the surgical form (tuberculosis of the bones, glands, and joints) is met with extraordinary frequency between the ages of five and fifteen. We cannot measure in exact figures the extent of surgical tuberculosis among Italian children, but if we accept the testimony given by experienced physicians in large hospitals, and the evidence gathered from the records of many pediatric clinics and dispensaries in various parts of the city, we must admit that it is exceedingly common among them.

The autopsies performed in the few cases allowed of Italian children have also shown a corresponding frequency of peribronchial adenopathy.

I do not believe that there is need of further evidence to prove that city congestion is detrimental to the health and life of Italian children. That is a commonplace and obvious fact. But in the case of the women, the effects of congestion on their death and morbidity rate are a more difficult matter to measure.

*RECRUITS EXAMINED AT THE ITALIAN GENERAL CONSULATE OF NEW YORK AND DEPENDING AGENCIES DURING 1907.

	ACCEPTED	SUBJECT TO A SECOND EXAM.	REJECTED

†In Italy the percentage of rejections ranges between 15 and 22 per cent., according to various provinces. In New York it is about 33 and 35 per cent.

MORTALITY OF ITALIAN WOMEN.

Studying the mortality of Italian women (and Italian adults in general) we are confronted with a peculiar contrast; the official statistics show a small death rate, especially in regard to pulmonary tuberculosis, yet we know—as all medical men, settlement workers, and others conversant with the situation know—that tuberculosis is very prevalent among them. The explanation of this discrepancy lies in the well-known fact that all adult Italians once affected by a serious disease, and so informed, board the first steamer and go back to Italy to die among the vines and orange groves. We cannot, therefore, gauge the mortality of Italian women from the tables of the Health Department, where they contribute only a small percentage (deaths from the very acute diseases, surgical operations, puerperal infection, etc.), but should count the wan-faced women that crowd the steerage of departing ships, or we should search the Bureaus of Vital Statistics of the little towns in Calabria or Sicily, where they swell the local death rate, and import from America tuberculosis where first it was unknown. The vast number of returning consumptives—both men and women—has taken such proportions of late that the Italian Government is considering special measures of quarantine both on board the ships and the point of debarkation. One little town in Sicily (Sciacca), whose inhabitants live in New York, all on Elizabeth street, between Hester and Broome streets, has established a small sanatorium on the outskirts of the city to receive the returning consumptive emigrants, so as to protect the rest of the population.

Studying the figures of those who return home from North America through the help of various benevolent institutions, we get an approximate idea of this phenomenon. The total number of those assisted with free passage from the Italian Benevolent Institute of New York in the five years, 1901-05, was 973, made up as follows: From December 5 to 31, 1901, 114; 1902, 209; 1903, 148; 1904, 266; 1905, 236. (Report of the "Istituto Italiano di Beneficenza," March, 1906.) Fully one-third of these were women, and tuberculosis, in almost all the cases, was the disease certified to obtain free passage. The total number of emigrants who returned to Italy in 1906 was 81,412, of whom 5.61 per 1,000 were cases of advanced pulmonary tuberculosis. (*Annals of Naval Medicine*, Vol. I, 1907.)

Studying further the mortality from tuberculosis of Italian women in New York, we find that they contributed 23.98 per cent. of all the deaths occurring among them in 1902, as against 21.9 contributed by the men for the same period. This

higher death rate of Italian women above the men is quite in contrast with the general rule which obtains for the whole city, where males surpass the females in the proportion of 13 per cent. against 10 per cent. of all deaths for the same disease.

The cause of the higher susceptibility of Italian women to tuberculosis must be sought in the sudden change from the open air and free life of the fields to the seclusion and semi-asphyxiation of the tenement houses, where even those of the better class remain shut up for weeks and months.

In attributing this high morbidity of Italian women to congestion, I have just in mind the special class who do not attend to any other work except their house duties—a class which is much larger than commonly suspected, even among the peasants. Of course, for those whose constitution is sapped in the labor of sweatshops or other exhausting trades, urbanization is only responsible in a very limited sense for their physical breakdown. (Dr. A. Jacobi has illustrated in a remarkable pamphlet what is "the physical cost of woman's work." Its result applies most forcibly to the Italian women employed in the American factories.)

The table above presented shows the same higher death rate of Italian women above men in certain blocks of New York. In fact, the female death rate for all ages in Block A is 25.3, while the male death rate is 23.8. In Block F the female death rate is 25.03; the male death rate is 21.46.

More conspicuous is this difference between the ages of five and nineteen. Death rate between five and 19 years in Block A was 3.10 female, 1.44 male; Block B, 6.0 female, 2.10 male; Block D, 8.15 female, 6.25 male. From these last figures we see at a glance that urbanization exercises all its baneful influence and works its greatest injury among the girls at the critical period of puberty, and this more especially among those who arrive in New York, fresh from the country, between the ages of ten and twenty.

The hardships and privations experienced in their first struggle in the new city, coupled with the vile tenements and overcrowded rooms which they are compelled to occupy, explain their high mortality. Usually a family arrives and goes to live in a relative's flat, which is already crowded, and before it settles and finds work, is sheltered there, doubling and sometimes trebling the rate of overcrowding. I have seen girls so placed die from acute miliary tuberculosis, or pernicious anemia, in the first year of their landing in New York.

Tuberculosis of the adnexa and peritoneum is also seen with great frequency among them, and carries off many of the young Italian women. (Surgeons of great experience in our general hospitals can testify to the truth of this fact.)

Their early marriages, frequent pregnancies, and long periods of lactation are contributory factors, when we consider that the same conditions prevail also in their native land and do not affect their health in the same degree. Without question, then, their rapid deterioration and high mortality in New York must be charged against urban congestion as the principal factor.

MORBIDITY OF ITALIAN WOMEN.

Here we have a very elusive element to deal with, and while we see a large amount of sickness among them, it is practically impossible to reduce it to an arithmetical expression, and, therefore, we cannot make the evidence scientifically complete. Again, in examining the rate of sickness—and of course this applies with the same force to the study of the death rate—it is absolutely impossible to disentangle all the different factors inextricably intermingled one with the other (insufficient food, poverty, overstrain at work) and assign to each part the proportion they play in the causation of diseases. We must rely, therefore, chiefly on personal observation and accept the evidence in a broad line. From the study of eight hundred cases of tuberculosis seen by me in the last six years in hospitals and private practice, and carefully classified for analysis, I have been able to gather some very interesting facts on the relation of city life and the health of Italian women, and in a measure I must repeat here what I have previously written on the subject.*

In Regard to Age.

	0–15 Years	16–25 Years	26–45 Years	46 Years and Over
Male	26	162	108	33
Female	48	230	161	48

Examining the 800 cases under review, it is found that about one-half (392 cases; 162 men, 230 women) came to America between the ages of twelve and twenty-five, and were perfectly sound, physically, upon arrival. But the pernicious conditions of their new atmosphere, the unhealthy and crowded habitations, the long hours passed in the factories, the thousand privations imposed upon them by poverty, combined with the intense labor that, from a desire to make money, they push to utter exhaustion, without being sustained by food proportionate to the demands of the excessive waste and rapid growth of this period, all this explains in the clearest possible manner why so many young lives become an easy prey to tuberculosis in America. The invasion of the bacillus, indeed, is a simple coincidence in their already deteriorated constitutions. The coincidence, too, is to be found in the fact that the epoch of the greatest activity and spread of tuberculosis (fifteen to forty-five years) corresponds exactly to the ages of the greater contingent of Italian immigrants, as I have already pointed out at the start. Of the 233,546 Italian immigrants who arrived in New York in 1903, 81 per cent., or 197,267, were between the ages of fourteen and forty-five, and only 11,246 had passed the age of fifty.

The irrefutable statistics of Nagäeli inform us that at this period of life one-half the urban population is infected with tuberculosis, and that more than one-third of the deaths which occur are due to phthisis. This is precisely what we find to be true, even in a more marked degree, of the Italians in North America.

Touching the interval between the arrival of the immigrant and the appearance of disease:

Average Time From Arrival to Symptoms	1 to 3 Yrs.	3 to 6 Yrs.	6 to 10 Yrs. or More	Total
Of the women	85	340	146	481
Of the men	74	87	158	319

The women figure for the greater number in the period of three to six years; the lesser period (from one to three years) holding preferably with the young girls employed in tobacco factories, the seamstresses at home, and the young tailors.

In regard to certain regional elements.—The analysis of the 800 cases under review shows a very high percentage of tuberculosis among the Sicilians and those from the southern part of Italy in general, as compared with immigrants from central and northern Italy. The same, I am sure, would be true of all statistics which, instead of a small

*"The Italians in North America"; "The Prevalence of Tuberculosis Among Italians in the U. S." Milan, 1906.

group, would embrace immigrants from the entire peninsula.

The 800 hundred cases are subdivided in my classification as follows: Northern Italy, 96 cases (Genoese and Lombards in excess); Central Italy, 82 cases (those from Lucca and Piacenza in excess); Southern Italy, 315 cases (those from Basilicata, Calabria, and Molise in excess); Sicily, 307 cases (provinces of Girgenti and Catania in excess).

The great preponderance of Sicilian and Southern Italans must be interpreted simply as a parallel to the larger contingent of immigration from the south of Italy in the last ten years, rather than as an indication of special susceptibility to tuberculosis in these provinces.*

However, the fact remains undisputed, nay, confirmed, by daily observation that the peasant women from Calabria and Basilicata, together with those strictly primitive ones from the provinces of Girgenti and Caltanisetta, give in New York a very high percentage of tuberculous diseases compared with any other regions of Italy. They, in fact, more than the others, throw themselves headlong into the business of the making of cheap clothing, and rapidly fall away, working fourteen to sixteen hours a day in most confined quarters, stinting themselves in the matter of food, in dress, and in everything else.

Other direct injuries to the health of the Italian women referable to urban congestion, besides tuberculosis, have to be briefly enumerated and accepted as some sort of evidence of a general character, rather than positive facts of statistical deduction. The most frequent of these are: (1) Anemia and chlorosis in all its forms and stages. (2) Amenorrhea and dysmenorrhea, from arrested or defective development of the generative organs. (3) Retarded menstrual function. The average Italian girl in New York menstruates after the fourteenth and sometimes in the fifteenth year of age, while in Sicily the average period is at eleven or twelve and in the northern provinces at thirteen and fourteen years.† (4) Poor muscular development and loss of muscular tone due to lack of exercise and ill-ventilated rooms. One of the most frequent results of this muscular atony is a general displacement and fall of the abdominal organs (movable kidney, enteroptosis, etc.) with which 85 per cent. of the Italian women that present themselves for examination at gynecological clinics are afflicted. (5) Gastric and intestinal disorders (constipation, dyspepsia, etc.), the direct result of the ptosis just mentioned and of polluted atmosphere in close quarters, with all the attending symptoms of autointoxication (headache, irritability, emaciation, etc.). (6) Skin diseases, especially scabies, ringworm, eczema. (7) Finally specific diseases, as we have come to understand this vague term, meant to include lues and all venereal diseases. These are spreading with alarming rapidity among our immigrant population, are sapping the vitality of our young men and women and planting the seeds for the degeneracy of the race. In view of their extreme importance, I hope you will allow me to say a few words about them, overcoming the feeling that naturally exists in regard to this scourge and the moral repulsion you may feel against its discussion here. The death rate from venereal diseases among persons under forty-five years of age in the registration area of the United States in 1900 was higher for the Italians than for any other element of the white population; among persons of forty-five and over the Italians ranked fourth.

If we view these diseases in the light of their infectious and contagious character, we see at once the close relation they bear to congestion of population, and then we realize that we are confronted in this respect with a peril just as great as tuberculosis, that we cannot afford to ignore. "Those maladies are not necessarily venereal, nor always associated with guilt and immorality." It is in this tragic sense that I wish to bring them to the attention of this gathering, because the ravages we see among our immigrants are many times the result of innocent contamination in the homes of the poor and overcrowded.

"Gonorrhea and syphilis insontium," the scourges of the innocent, are more prevalent than people suppose. The literature has 9,058 cases of extragenital syphilis mostly innocently acquired (L. D. Bulkley). When people live huddled together at the rate of five and six in a room, it is impossible not to come in touch with the utensils, linen, bedding of persons infected with the disease, and in this way harmless children and honest women contract the virus without their knowledge, with no sin of their own. I shall not tell you of the hundreds of silent tragedies enacted in some poor, honest Italian family, where the presence of a chance boarder or a lodger brought the poison to the home. I shall not tell you of the cases of a child (fallen under my observation) who lost his eyesight in one night for having rested a while on the cot of a transient boarder. Nor of the hundreds of young girls of five and ten reeking with pollution accidentally communicated to them through bedding and towels and lack of sanitary conveniences in overcrowded tenements. And what about the thousands of innocent Italian women who have had their vital organs sacrificed and their health forever wrecked, after joining their long-departed husbands, only to be unknowingly contaminated by the deadly poison! This is already telling on the second generation of Italian women in America, who, in contrast to the phenomenal and proverbial fecundity of their mothers, are showing either "one-child-sterility" or absolute sterility.

Here is a problem that the Conference on Congestion of Population cannot afford to ignore and must not be ashamed to face. Despoil your mind of past prejudices in regard to these maladies: take off the adjective "immoral" from their name—because there is no question of immorality where innocent lives are constantly sacrificed — consider them as they are, contagious, highly infectious diseases, class them with smallpox, scarlet fever and diphtheria, and wage a merciless campaign against this domestic evil, that will free, if not mankind, at least the innocent and the honest from the worst blight that health could ever suffer.

The luetic scourge and the venereal diseases in general are chiefly diseases of cities, and it has been

*The geographical distribution of tuberculosis in Italy shows, on the contrary, the very opposite condition, in that the death rate from this disease is lowest in Sicily and the southern provinces in general, especially along the eastern coast (14-16 per 10,000 in the Province of Messina) and highest in the northern part, as in Leghorn, Milan, Genoa, and Venice (30-32 per 10,000). (Prof. G. Sormani.)

†According to Dubois and Pajot the different ages at which menstruation appears are: Warm climate, 11 to 14 years; temperate climate, 13 to 16: cold climate, 15 to 18.

Age at which menstruation appears in girls of the rich and the poor, in Italy. (Marro: "La Puberta," Turin, 1901.)

Years	Rich	Poor	Years	Rich	Poor	Years	Rich	Poor
10 years	1.3	1.7	14 years	20.0	21.4	18 years	1.3	...
11 "	13.3	5.3	15 "	8.4	30.3	19 "	1.3	...
12 "	18.7	7.1	16 "	4.0	16.0	20 "	...	...
13 "	29.3	8.9	17 "	2.6	8.9			

estimated that there are no less than 50,000 new cases of specific infection in New York every year. In the absence of compulsory notification, it is impossible to measure its extent, but you would be amazed to know how many have had some form of specific infection when you take the history of patients. Among Italian immigrants, especially among the women and children who come from rural districts where the disease is practically unknown, the infection that takes place when they arrive in New York is in 40 per cent. of the cases innocently acquired. Many mothers of the poor who take children from institutions to nurse them have also been inoculated with the poison. I have personally known of a case, where the infection, not soon recognized on account of its extragenital origin, was communicated by the mother to four of her children, to her husband and one sister.

Those, in a large measure, are the evils caused by congestion, and these the physical results of overcrowding on Italian women and children. The moral effects are just as great and serious. The homelessness of the tenement and the absolute absence of privacy of family life, make the abode of the poor one of the greatest perils of modern civilization. Already the children of the Italian immigrant have cut loose from paternal authority, do not resemble or imitate the fathers in the purity of the home and the strength of family ties, and they are contributing a large share to the juvenile courts and reformatories.

They are only the results of bad and vicious environment; they are temporary evils of a race climbing upwards and the inevitable set-backs of a people trying to adjust themselves to new surroundings. In other words, they represent conditions of a transitional stage, that will right themselves.

Let us arrange for a better distribution of the immigrants *not after* they have reached Ellis Island, but *before* they decide to leave their motherland, by informing them of the wonderful resources of this vast continent, outside and beyond the large cities; let us educate them to the principles of hygiene and life, when they are settled here, and above all, let us distribute the work in appropriate areas outside of the city limits, so that proximity of the factory should not be as it is now, in a large percentage of the cases, the chief reason for their congesting the cities. Let us, finally, promote the building of model tenements at a low rent that will not absorb 33 per cent. of their income, and stimulate the philanthropy of the rich in this direction, and when we shall have given the people clean, healthy homes, full of light and sunshine, we shall have accomplished the physical and moral regeneration of the masses; we shall have given them that to which every human being is entitled, health and happiness.

214 East Sixteenth Street.

THE FIFTH NERVE IN RELATION TO OPHTHALMIC CONDITIONS.*

By SAMUEL HORTON BROWN, M.D.,

PHILADELPHIA.

In presenting this subject, it, perhaps, becomes me, first, to apologize for the trite character of the facts that I shall bring before you, but as the object is merely to renew or awaken interest in those features of ophthalmology that are seldom touched upon, I feel justified in inciting this academic discussion.

*Read before the Wills Eye Hospital Ophthalmological Society, January 6, 1908.

When it is considered that all the afferent impulses connected with ocular structures, with the exception of those directly concerned in the special sense of sight, and perhaps trophic impulses, are carried by the fifth nerve through its large branch, the ophthalmic, the necessity of a proper understanding of its distribution becomes at once obvious. Turning for a moment to its anatomical consideration. (Hardesty's description in Morris's Anatomy, 4th edition, 1907), we find that "the sensory root of the trigeminus may be traced through the Gasserian ganglion into the cerebellum and into the terminal nucleus of the pons. After leaving the semilunar (Gasserian) ganglion, in pursuing its course toward central structures, it gives off T-shaped fibers which divide into peripheral and central branches. The central branches divide into ascending and descending branches on entering the brain-stem and find their nuclei of termination in a dorsolateral column of gray substance, which consists of the upward continuation of the gelatinous substance of Rolando of the spinal cord. Opposite the entrance of the nerve the column becomes somewhat thickened, constituting the sensory nucleus of the trigeminus, the part below being known as the nucleus of the spinal cord. The branches of the entering fibers bifurcate and terminate about the cells of these nuclei. The descending branches are longer and, passing downward, form the spinal tract of the trigeminus, which may at times be traced as far as the second cervical segment of the spinal cord. The ascending branches are short and terminate, as a rule, in the sensory nuclei."

"The axones from the nucleus of termination are distributed to the nuclei of its motor portion of the same and opposite sides; to the nuclei of the motor cranial nerves, and to the thalamus of the same, and chiefly the opposite side. The sensory nuclei are connected with the somaesthetic area of the cortex by the fibers of the medial lemniscus (fillet) and with the motor nuclei of the other cranial nerves by the medial lemniscus."

While the motor root of the fifth nerve is not directly connected with any ocular functions, it may be well to trace its origin in order to show the close association with the nuclei of other cranial nerves. "The nucleus of origin of the motor root of the trigeminus is composed of two portions. The principal nucleus lies on the dorsomedial side of the sensory nucleus. It gives rise to the greater part of the motor root and its fibers are distributed to the muscles of mastication. Above the principal nucleus and along the line of the locus cœruleus extends the nucleus of the mesencephalic (descending) root. The cells of this nucleus are thinly scattered as high up as the posterior commissure of the cerebrum and the mesencephalic root arising from them gradually increases as it passes through the encephalon to the superior level of the pons, where it joins the fibers arising in the principal nucleus. The distribution of the fibers of the mesencephalic root is not clearly settled. The motor nuclei of the fifth nerve are connected with the lower part of the somaesthetic area of the cerebral cortex of the opposite side by the geniculate bundle of pyramidal fibers, and they are associated with the sensory nuclei of other cranial nerves by the medial longitudinal fasciculus. Thus it will be readily appreciated how closely related are the central portions of this nerve with the central portions of other cranial nerves, sensory as well as motor, and it is scarcely conceivable, in view of this, that they do not have some common functions at least."

So much for the detail of the central distribution

of the nerve. As we all know, the peripheral distribution is through three large branches, the ophthalmic, the maxillary, and the mandibular. The ophthalmic is exclusively sensory, and before it divides into frontal, lacrymal, and nasociliary (nasal) nerves, it receives communicating filaments from the cavernous plexus of the sympathetic and likewise communicates by three branches with the third, fourth, and sixth nerves. This affords a structural explanation of some of the peculiar associated extraocular muscle-palsies and other muscle phenomena, such as twitching of the lids, blepharospasm, etc. Later in its course, through the medium of its nasociliary (ganglion) branch it communicates with the third (oculomotor) nerve and filaments from the cavernous plexus of the sympathetic. The long ciliary nerves are branches of the nasociliary (nasal) branch, while the short ciliary nerves are derived from the ciliary ganglion, which receives its sensory root from the nasociliary (nasal) nerve. Thus it will be seen that sensory impulses except those directly referable to the sense of sight are carried by the fifth nerve, most by the ophthalmic, a few by the maxillary branch. Ocular pain is made possible only through the fifth nerve. The other nerves arising from the fifth nerve are distributed to certain of the muscles of mastication and to the teeth. Through the superficial communication with the facial nerves, pain arising from diseased conditions of the face may be referred to the eye and *vice versa*.

Having disposed of the anatomical conditions, it is necessary, for argument's sake, if for no other, to enumerate the conditions that have been observed to illustrate the relationship assumed at the beginning of this paper. Beginning with the skin of the eyelids, perhaps the most common is herpes zoster ophthalmicus, a clinical variety of ordinary shingles. This follows the peripheral distribution of the fifth nerve and not uncommonly involves the cornea with destructive results. Very occasionally, according to De Schweinitz, atrophy of the optic nerve and paralysis of the oculomotor nerve have followed this affection, showing the trophic influence of the fifth nerve.

Leprosy, an uncommon condition with us, often begins about the eyelids, and is characterized by cellular deposits about and within the nerve, thereby producing anesthetic areas. This anesthesia in leprosy is not confined to the eyelids, but likewise involves the cornea. Anesthetic areas over the distribution of the ophthalmic nerve in the course of hysteric affections are within the range of possibility, but it is doubtful if such details have been recorded. A peculiar hysteric affection has been reported by C. Markus (*Ophthalmoscope*, January, 1907), which was manifested by tonic contraction of the right frontalis, resulting in a continuous elevation of the right eyebrow. This was not compensatory as is seen in ptosis. There was twitching of the left supercilii and the right pupil was slightly larger than the left. The patient was the subject of almost continuous left-sided headache.

Tonic cramp of the orbicularis (blepharospasm), due to the irritation of foreign bodies in and inflammation of the conjunctiva or cornea is by no means uncommon and owes its production to irritation of the terminal filaments of the fifth nerve. Not only does this reflex action find its expression in this tonic spasm, but pain, photophobia, lacrymation, and redness in anterior ocular structures may be attributed to it. The relation of conjunctival disorders to the fifth nerve is no better illustrated than in the case reported by T. H. Butler (*Ophthalmoscope*, May, 1907), in which mydriasis accompanied conjunctivitis. This was doubtless caused by the reflex arc produced by the communication between the fifth nerve, the sympathetic, and the third nerve. The condition known as snow-blindness, conjunctival asthenopia, etc., is in all probability intensified by some neuropathic factor involving the nerve under consideration, since exposure of other mucous membranes to the same conditions would not be productive of such annoying symptoms. Conjuntivitis has been attributed to teeth disorders by Förster, Kempton, and others in certain cases and relieved by the extraction of the offending teeth.

While most of this apparent relation is speculative, it is possible to point to a tangible connection between the trigeminus and many forms of corneal ulceration. Indolent ulcers, dendritic ulcers, ulceration associated with carious teeth, neuroparalytic ulcers, etc., are acknowledged to be dependent upon the disturbance of the trophic influence of the fifth nerve. In neuroparalytic ulceration we find anesthesia of the cornea as in lepra, herpes corneæ (Horner), and glaucoma. Here the condition is secondary to a severance of the trophic impulses while in other ulcers we find neuralgic pains and increased sensibility dependent upon an increase of sensory impulses. Trophic changes are well illustrated in those corneal conditions associated with Hutchinsonian teeth and rachitic teeth. The influence of the fifth nerve in this connection is obvious.

H. Powers (Trans. Odont. Soc. Great Britain, London 1883-1884, XVI, p. 56) years ago in a detailed study of the relationship existing between the teeth and the eyes called attention to the occurrence not only of corneal ulceration but also glaucomatous symptoms, mydriasis, myosis, paralysis of the extraocular muscles, failure of accommodation, and exophthalmos in the course of dental disease. On the other hand, Stevens, in 1877, reported a case of obstinate toothache relieved by wearing cylindrical lenses, an experience which is by no means novel at this date.

In connection with affections of the iris, it may be assumed that pain is directly due to involvement of the fifth nerve, since it is the sensory nerve of that structure The possibility of the fifth nerve being the intermediate factor in those cases of mumps attended with iritis is worth investigating. True iritis has been shown to have produced neuralgia directly referable to the teeth by Galezowsky (*Journal d'Ophthalmologie*, tome i) and others. Cyclitis secondary to dental disease has been observed by Juler. The ciliary nerves as a factor in the pathogenesis of sympathetic ophthalmia is still entertained by some observers (Schmidt-Rimpler) despite the great vogue the toxin theory is now enjoying.

Glaucoma with its corneal anesthesia, neuralgia, and trophic changes in the optic nerve, certainly is attended with involvement of the fifth nerve, but whether the disturbance of the trigeminus is a primary condition has yet to be proved. Donders inclined to the belief that hypersecretion superinduced by irritation of the fifth nerve, was the cause of the disease. While this theory is no longer entertained, it is interesting to note that the influence of this nerve was the subject of thought at this period. Those cases that have obtained benefit from the Jonnesco operation incline one to regard this older theory of the influence of the trigeminus with some favor in view of very close association of its fibers with those of the sympathetic within the orbit. Badal in 1882 advocated stretching of the nasal nerve for the relief of ciliary pain and

the procedure has since been applied to the treatment of glaucoma by Trousseau, Abadie, Lagrange, Ulry, Ginestous, and others. As recently as September, 1906, Villemonte (*Recueil d'Ophthalmologie,* September, 1906) revived the operation making claims for its value in secondary glaucoma, keratoiritis, ulcerous keratitis with secondary glaucoma, chronic glaucoma, and secondary glaucoma occurring in the course of hemorrhagic retinitis and neuroretinitis.

Among the less frequent causes of lenticular opacities may be mentioned the irritation of the fifth nerve incident to dental disease. Such a case has been recorded by H. Sevill (*Lancet,* 1884, p. 709) although it may be regarded with scepticism. Chorioiditis and vitreous opacities have been observed to follow dental disease by M. Juler. Perhaps the greatest influence of the fifth nerve as regards dental disease is to be observed in those cases in which there is disturbance of the extraocular muscles. Spasm of the eyelids (S. J. Hutchinson, *Medical and Surgical Reporter,* 1885), ptosis, and strabismus (Hancock, *Lancet,* 1859) have been recorded. The accommodation has been reflexly affected by dental disease as is shown by Herman Schmidt's (*Archiv für Ophthalmologie,* XIV) analysis of ninety-two cases of dental disease in which seventy-three instances of deficient accommodation were noted. Reflex blindness has been attributed to the fifth nerve in certain cases associated with dental disease (Brubaker; Allport, *Journal of the American Medical Association,* 1883, p. 637; Dewitt, *American Journal of Natural Sciences,* CX, 1868, p. 382).

While the views of different observers vary greatly as to the real influence of the trigeminus in the cases cited, it remains certain that the close association of the nerve, both centrally and peripherally with the other nerves must of necessity have some close association functionally or pathologically, and it is only with the purpose of reviving an interest in the possibilities, suggested by the anatomy of the nerve, that this essay is written.

1901 Mount Vernon Street.

A PIECE OF CATHETER VOIDED DURING URINATION.

By WALTER S. REYNOLDS, M.D.,

NEW YORK.

CHIEF OF CLINIC AND INSTRUCTOR IN GENITOURINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY).

In calling attention to the following case which recently came under my observation I do so not only on account of its interest because of the rarity of such an occurrence, but also for the practical lessons it teaches.

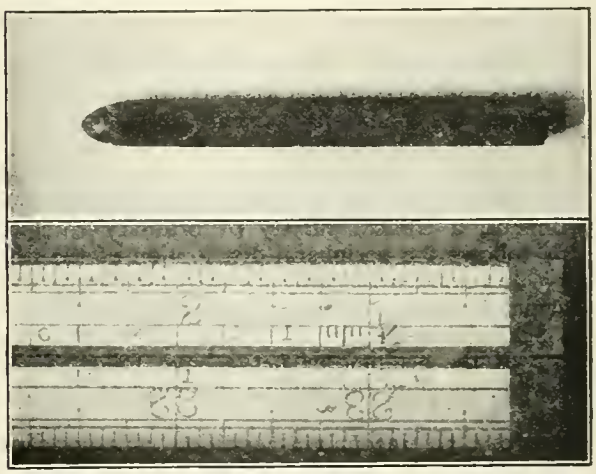
The patient was a man twenty-three years of age, who came to the Vanderbilt Clinic complaining of painful and frequent urination, which he had been suffering from for the past nine months. He denied ever having had gonorrhea, but had acquired syphillis five years previously. For this he had been treated for six months at the Lock Hospital, London, and since that time there had been no manifestation of the disease.

He had been obliged to urinate about every hour during the day and two or three times at night. Urination was very painful, but the urine was passed freely and easily. So far as he was aware there had never been any blood in the urine. A short time before coming to the Clinic he had made four or five visits to a physician, who at first prescribed some remedy, assuring him he would soon be well. On the last two visits the physician had passed a catheter and irrigated the bladder. Following these treatments his symptoms had become worse, and when he again consulted the physician he was told that he had something growing in his bladder and an operation would be necessary.

On his first visit to the Clinic the urine was cloudy from pus and contained shreds. An examination of the prostate showed it to be somewhat large and more tender than normal. The condition was considered too acute at that time to permit of cystoscopic examination; he was therefore ordered an alkaline diuretic mixture and hot sitz baths night and morning. On returning one week later the condition was reported to be about the same. He was told to return a few days later, when an examination of his bladder would be made, if possible.

Five days later he returned, stating that on the previous day, while urinating, he had passed a piece of catheter, which he had brought with him. The illustration is from a photograph of this, in actual size.

I examined him for the first time two days subsequently and found his urine clear, only containing a few flakes and shreds. The frequency of urination was somewhat diminished and the pain was less, though the frequency was still more than normal.



The piece of catheter measured two and one-fourth inches in length and was of No. 16 F. scale. An examination of the piece showed it to have been apparently little used, as it retained its original color, not having become discolored or stained from long usage. At it was desirable to retain the specimen in its original condition, no attempt was made to test its friability.

The case was to me unique at the time, not being able to recall to mind the record of a similar case, although Gouley states that "fragments of catheters, pistol bullets, and other small objects have been passed from the bladder into the urethra to be carried away by the urinary current." I have since come across two cases recorded in the Medical Record, one by Dr. C. C. Ransom, in which the patient in catheterizing himself broke off a piece of webbed catheter six inches long, and finally succeeded in extracting it himself by passing another catheter and telescoping the broken piece. In this case it seems quite evident to me that the catheter must have been lodged in the urethra. The other case is recorded by Dr. W. B. Davis; the man passed the piece during urination, after being ordered to eat a large quantity of watermelon and retain the urine for some time.

The patient was recently shown at the American Urological Society and none of the members had seen a similar case. There was some doubt expressed by one of the members as to whether the catheter had been broken off in the bladder, and that possibly it had been retained in the urethra, the urine passing through the catheter. This, of course, might have been the case, and to learn, if possible, if this was so, I questioned the patient as to the manner in which the piece had been passed out, but he was unable to give me any information on that point.

If all the facts are as the patient stated them it serves very well to illustrate how important it is in purchasing catheters to buy only those of the best quality. Cheapness is an item not to be considered. It must also be remembered that all articles of this sort deteriorate quite rapidly, more especially if not in constant use, on account of the oxidation which takes place. A catheter which has remained for some time unused should always be thoroughly tested before being passed into the urethra to satisfy oneself that it is sound.

If any one should be so unfortunate as to have such an accident occur, the best course to pursue would be to inform the patient of the fact, and if the physician could not remove the piece himself, send him to some one who could.

As to the best method of treatment in such a case, if the piece was lodged in the anterior urethra an attempt might be made to remove it by manipulation of the urethra from below and behind the fragment, the urethra being well distended with olive oil. Calculi have in some instances been removed in this manner. At the present day, when nearly every one is using the endoscope, a resort to such measures would be unnecessary, as the foreign body could be easily seen and grasped through a good-sized tube and easily extracted.

If the fragment was lodged in the bladder, a cystoscopic examination might be of assistance, and if the piece was quite small it might be extracted with the operating cystoscope; though, as a general rule, I should be opposed to the use of such an instrument, both on account of the traumatism which might result, and also because, in my experience, it is extremely difficult to grasp the fragment. External urethrotomy would be the method of choice in such a case, when the piece could be grasped and easily removed.

A great many have probably seen very fair-sized stones which have been passed, and there is no reason why a piece of catheter of the size shown should not be voided, provided it gain entrance at the internal meatus. But this would probably very seldom occur and it would be worse than useless to wait for such an occurrence in the majority of cases.

Whether the piece was broken off in the urethra or had lodged in the bladder, the patient may be considered as having been very lucky.

INUNCTION OF IODOFORM IN TUBERCULOUS PERITONITIS.

By SIDNEY F. WILCOX, M.D.,

NEW YORK.

Iodoform has long been recognized as the most powerful agent for the local treatment of tuberculosis. It acts directly on the bacillus, but in order to obtain its bactericidal effect it must be brought into direct contact with the organisms.

As a dry powder, iodoform is as inert as so much sand, and it is only during the process of change from iodoform to iodine that its power is exerted. It is not as iodoform that it acts, nor as iodine, but in the stage of transition, or in the form of nascent iodine.

To induce this change the iodoform must be brought into direct contact with such liquids as have the power to break it up and make it available. Pus has this property; the liquid contents of a so-called tuberculous abscess has it also, and that is the reason for the activity of this agent when brought into contact with these liquids. This is true whether the iodoform is introduced into sinuses of pus cavities, either as a powder or in suspension in oil or glycerine, or in an ethereal solution.

The introduction of iodoform into a sinus or closed sac is easily accomplished by packing in the dry powder in the first instance or its introduction as an ethereal solution or in suspension in oil or glycerine after aspiration of the fluid. Here the iodoform which is left after the absorption of the oil or evaporation of the ether is in actual contact with the diseased tissues and exerts its destructive effect upon the bacilli. This I have been able to demonstrate in many cases of tuberculous joint disease, with the result of obtaining complete cures even in the advanced stages.

In cases of tuberculous peritonitis it would not be possible to bring iodoform powder into actual contact with the disease focus without an operation (as has been done) and it was with the idea of rendering iodoform easily absorbable through the skin that I was led to make up the solution which I employed in the two cases given below.

The only easily obtainable solvent of iodoform that I know is ether, which takes it up in the proportion of one part to ten or twelve. This solution is unstable and is not adapted for inunction because the ether evaporates immediately leaving a deposit of dry iodoform on the surface. An iodoform ointment is made by stirring the powder up with vaseline, but in this case the powder is simply in suspension and not in solution, although by inunction a certain small amount of the iodoform may be rubbed into the skin with the vaseline, and good results have been obtained by the use of this mixture.

It seemed to me, however, that if the ethereal solution of iodoform could be added to an oil it would remain in solution and so be much more readily taken up, and as ether and oil unite in almost any proportion, I simply made up an ethereal solution of the drug and poured it into the bottle of oil, with which it made a perfect solution. The proportions may be varied, but the one which I have employed the most is: Iodoform, ʒij; ether, ʒijss; add olive or cod liver oil to make ʒviij. This is applied by inunction to the abdomen night and morning.

Case I.—About eighteen months ago a delicate looking girl of fifteen years was brought to my clinic at the New York Medical College and Hospital for Women. She was anemic, had never menstruated and had marked enlargement of the abdomen which had given rise to unjust suspicions of pregnancy. The abdomen was as large as that of a woman six months pregnant. The enlargement was symmetrical, but was flatter in the recumbent position than in the case of an enlarged uterus. Dullness was present, but it changed location from day to day, although the presence of free ascitic fluid could not be determined. It is probable that the fluid trickled slowly between adherent folds of intestines as she changed position. She had no cough or evidence of pulmonary involvement, but her mother had died of consumption.

Shortly after admission to the hospital she had a run of fever with some spots on the abdomen, which led to the idea of possible typhoid, but it quickly subsided under treatment, although the abdominal enlargement continued to increase.

Finally, a diagnosis of tuberculous peritonitis having been made, I decided to open the abdomen to give her the benefit of the well known good effect of simple incision in such cases. Through a median incision I reached the peritoneum, which was greatly thickened and intensely red. On attempting to open it I found it so firmly adherent to the other structures that I abandoned the attempt after having simply split the thickened membrane without opening the abdominal cavity in the slightest degree. The wound was closed and healed within a few days. Then I began the inunction of the iodoform solution mentioned above, and after a few weeks the abdominal enlargement entirely disappeared. She improved in health, her menses came on, and she looked like a well girl. I had not see her for nearly a year, when she came to see me a short time ago. I did not have time to make a thorough examination then nor have I seen her since, but there is no abdominal enlargement: she is in pretty good flesh, but for the last two months the menses have not appeared and she is not feeling well—and I fear there is a possibility of impending pulmonary trouble—especially as she has been working where the hygienic conditions are not good.

Case II.—This is a case of a boy four and one-half years of age whom I had had under my care for eighteen months for Pott's disease of the spine. He had also during that time developed a tuberculous mastoid abscess which had been operated on and cured by Dr. F. H. Boynton. The nurse called my attention to a very marked enlargement of the abdomen, and on examination I found free ascitic fluid. The same method of treatment was prescribed as in Case I, and within a short time the fluid disappeared, the abdomen became flat, and the general health improved. It is stated by authorities that some cases of tuberculous peritonitis in children get well spontaneously. Admitting that as a possibility, I do not believe that such a probability existed in these cases. Nor do I believe that the operation in Case I had anything to do with the cure.

Some time before I employed the solution here mentioned my friend the late Dr. H. M. Dearborn consulted me about a case of irregularly lumpy enlargement of the abdomen. I did not see the patient, but judged the condition to be one of tuberculous peritonitis and advised the use of iodoform rubbed up in vaseline, by inunction. This was used with a resulting cure.

Three cases are of course not a sufficient number upon which to base a definite conclusion, but these results indicate a method of treatment which may be of value. It seems to me that benefit *might* be obtained by inunction of the ethereal solution in cod liver oil or olive oil over the chest in cases of pulmonary tuberculosis or possibly even in tuberculous meningitis. I will add that in one case in which the knee joint became enlarged and tender about two weeks after I had made a resection of the hip joint, the solution was applied daily with the result of complete subsidence of the symptoms.

41 West Fifty-second Street.

Cremation in Prussia.—The Prussian Government is about to abolish the existing Ministerial ban against cremation. This subject has been under active discussion for about twenty years, members of the Conservative and Clerical parties steadily refusing to grant the concession.

The Tomb of an Ancient Egyptian Physician.—Garstang's recent work on the "Burial Customs of Ancient Egypt," gives a scientifically complete record of the contents of the sepulcher of an Egyptian physician, and in this case of a personage who flourished under the twelfth dynasty, *circa* B. C. 2000. The deceased, whose tomb is described, was named Nefery, and in all the numerous repetitions of his name upon the two coffins provided for him is termed "a physician." That he either came of a wealthy family or amassed wealth by the practice of his profession is proved by the expense that was lavished upon his burial, his funerary furniture being one of the most complete sets of such appointments found in other than princely tombs at Beni-Hassan, where he was interred. Various and many as were the objects deposited beside his body, only two of these can in any way be considered as connected with his vocation. These are a set of writing implements, consisting of a writing tablet and a pen box, the latter furnished with a number of reed pens ready for use. The writing tablet, which, together with the pen box, was placed upon the lid of the outer of Nefery's two coffins, was coated with stucco and then painted, and the surface so carefully smoothed by some polishing process that it was probably possible to remove any temporary memoranda made thereupon as soon as their purpose was fulfilled. At one end of the pen box were two inkwells in which the remains of a red and of a blue-black ink can be detected. Unfortunately no written notes survive upon the palette. Among the objects found in the tomb are some beautiful models of Nile boats, one having twenty rowers; also an imitation of a granary and many figures of domestics and laborers. The inner coffin, or sarcophagus, bore some quite new texts to scholars of the most archaic Egyptian religious books and explained that Nefery was a devotee of Osiris. The body had been laid upon its side wrapped in folds of linen cloth and was not mummified. The head was encased in a painted cartonage. This physician's tomb has been rearranged, as it was when first reopened, in the Cairo Museum, where it is the subject of much interest.—*The Lancet.*

Hemoglobin and Iron in the Blood of Infants.—Luigi Giordani details examinations made of the blood of infants suffering from various diseases, as to the amount and composition of the hemoglobin and iron in it. The iron found in the blood is supposed to be mainly in composition with the hemoglobin, but there is also some iron not contained in the hemoglobin. A part is in the plasma, due to the destruction of the blood corpuscles, and another part is under the form of albumin or nuclein in the leucocytes, derived from the metabolism of feruginous foods. The liver contains much iron, which is thrown into the circulation at various times. From the eighty-six cases examined by the author, in twenty-two there was increased amount of iron, in thirty the hemoglobin was in greater amount. Tuberculosis acted on the hemoglobin and its compounds to diminish them. There was a large amount of iron found in nursing infants, especially in the extrahemoglobinic form. A certain amount came from the liver, while some came from the new formed blood corpuscles. The iron and the hemoglobin do not always bear a constant relation to one another.—*Gazzetta di Roma.*

Experimental Atheroma and Ovariotomy.—L. Lortat-Jacob and Ch. Laubry detail experiments made on animals to produce atheroma, and to ascertain the relation of the removal of the ovaries to its occurrence. Their conclusions are given thus: 1. Certain physiological conditions, such as sex, age, and lactation, explain the negative results obtained in rabbits in attempted production of atheroma by injection of adrenalin. 2. Castration of the animals favored the production of atheroma in the females. 3. In those animals that had had the ovaries removed there was a marked accumulation of fat instead of atheromatous lesions produced.—*La Tribune Médicole.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 2, 1908.

POLYCYTHEMIA.

CONDITIONS involving quantitative and qualitative changes in the white blood corpuscles have received a great deal of attention ever since the improved technique elaborated especially by Ehrlich and his pupils has enabled us to recognize the various types of these blood elements. In addition to what may be called symptomatic changes in the leucocytes, such as absolute and relative leucocytoses and leucopenias, a distinct class of diseases of the blood itself, the leukemias, has been discovered. The ultimate factors underlying these conditions have not as yet been found, though the real seat of the disease has been demonstrated to be in the blood-making organs of the body.

Quite recently Osler has collected a number of cases of disease similar to the leukemias in type, but involving not the white but the red corpuscles of the blood. It is probable that Vaquez, in 1892, had published the first recognized case of this affection; since then some twenty-five cases have been reported, characterized by a great numerical increase of the red blood cells accompanied usually by cyanosis and enlargement of the spleen. In Nos. 7, 8, and 9, Vol. VII. of *Russkii Vratch* Dr. G. P. Rubinstein communicates one more case of the disease, and at the same time subjects to a careful analysis the data obtained by the earlier observers. He finds that of the three elements usually entering into the clinical picture of the disease, that is, polycythemia, cyanosis, and the enlargement of the spleen, but one may be considered as constant and characteristic, namely the polycythemia. The cyanosis has been absent in three reported cases of the disease and in a case of Dr. Strigenko not yet reported. This so-called cyanosis, moreover, is quite different in character from the appearance produced by the diseases of the heart and lungs. The color of the skin is not bluish-black but rather of a purplish or violet-red tinge, depending, as it does, not upon the backing up of the blood in the veins but upon the great increase of the hemoglobin and upon the dilatation of the capillaries caused by the increase in the corpuscular elements of the blood. The appearance really simulates a hyperemia of the skin, differing from the usual acute condition by returning but slowly after the application of pressure and by involving such sites as the tongue and the vocal cords. The second element, the enlargement of the spleen, has been absent in a number of reported cases. That it has no causal relation to the disease may perhaps be concluded from the fact that in one case of polycythemia (Caminotti) the condition of the blood was found to be unchanged seven years after the removal of the enlarged spleen.

Polyglobulism, however, forms the essence of the disease, and all questions of the etiology of the affection are concerned with the explanation of this phenomenon. The change in the corpuscles is mostly numerical in type, although a few normoblasts are found in the circulating blood. The number of red cells observed has been from six to twelve million per c.m., which forms a curious commentary on the views of Reinert, who has concluded from mathematical and theoretical considerations that the greatest possible increase of the red cells in man could not exceed some nine million cells to the cubic millimeter! The white cells are also somewhat increased in number, the polymorphonuclear forms showing both relative and absolute increase; most of the cases have likewise shown a few myelocytes and mast cells. The essential pathological lesion has been found to be a marked hyperplasia of the erythroblastic apparatus of the body, expressed in the transformation of the usual yellow medullary contents of the bones into an active red marrow. This pathological finding immediately classes the disease as an analogue of the leukemias, and in recognition of this the author proposes a new name for the condition which may be translated from the original Russian by the term "*erythemia.*" In the one case the leucoblastic apparatus is involved in the lesion, in the other the erythroblastic portion is the one affected. The seeming differences in the types of the changes observed in the two corpuscular elements of the blood may be explained, according to Rubinstein, by the existence of but one normal type of the red cell, which of course limits the possibilities of variation, and by the fact that the evolution of the red cell is much more rapid than that of the more highly organized leucocyte. The differences observed are thus conditioned by the marked physiological demarcation between the elements affected in the two conditions. Whether the ultimate causes underlying these diseases are the same or not remains to be cleared up by future observations.

Dr. Rubinstein's analysis sums up very clearly our present knowledge of the subject, and the term proposed by him is preferable to polycythemia, which may remain to designate symptomatic increase in the number of red blood cells; it is certainly more acceptable than the pseudo-complimentary eponyms, such as "Vaquez' disease" and "Osler's disease" that are sometimes used in describing this rare affection.

THE ARMY RIDING TESTS.

THERE is a neglected medical side to the army horsemanship tests which have been filling so much space in the newspapers. As every physician knows, the heart can stand only a certain amount of internal hydrostatic pressure, and any excess results in acute dilatation. If the person is young and the stretching is not excessive the heart may recover in a few minutes or hours as it is elastic in that sense, but in those who are beyond the age of 35 or 40 there is apt to be permanent dam-

age. It is almost a daily routine of some consultants to advise men over 40 to abstain from excessive muscular activity. The medical profession some years ago put a stop to the bicycle craze which ruined so many old men, and it is responsible in part at least for popularizing such games as golf, which can be safely played in extreme old age.

From time immemorial the muscular exertions in armies have been performed by young men—mere boys—and even they can not stand the stresses of a long war—no human being can. But it is found that boys, though they have the proper muscles and hearts, are not possessed of sufficiently matured brains, and even if they had the brains, they have not the experience or training to enable them to do the mental work. For thousands of years it has been found necessary to have mature, even elderly, leaders commissioned for their mental abilities and relieved from all the muscular strains which only young men can perform. This distinction between officer and soldier is a physiological necessity and arose as a matter of experience, for warfare is impossible in any other way. Never, except in prehistoric savagery when armies cannot be said to have existed, have the leaders been supposed to be able to do the actual fighting. Yet recently the War Department has been bent upon exacting of officers over forty exertions which are proper for youthful men only.

The latest proposition is to compel all officers to take a ride of thirty miles for three successive days, and on each day covering five of these miles on foot leading the horse. It is safe to say that not one of the elderly officers who fought the Manchurian campaign was ever required to do anything approaching this in severity. If it had been exacted as a test beforehand it is certain that the war would not have been fought, for officers would have been lacking. Marshal Oyama and his generals could not have endured it, judging from their pictures and such descriptions as have been published. If it is required here, our army will be deprived of many of its valuable officers fit for campaigns, and many of those who do take the test will be ruined for the less strenuous exertions of actual war. In other words, the test is beyond human endurance, except for freaks or cowboys less than 40 years old. Even the former test was too severe and rumor credits it with having done more or less damage to some of the officers. Training is designed to fit men to stand the strains of war with the least harm, and to expose them to the dangers unnecessarily is as foolish as exposing them to gun fire to get accustomed to being fired at. But in this case, the officer will seldom if ever be subjected to such strains even in war, and it is amazing that they are suggested. There must be something wrong with the army when medical science is so ignored.

CONSERVATIVE GALL-BLADDER SURGERY.

While it is certain that removal of the gall-bladder often seems to affect the general health in no appreciable way, it would yet be rash to assert that the gall-bladder does not serve a useful purpose. The fact that a diverticulum from the stump of the cystic duct or along the course of the common duct occasionally develops after cholecystectomy is at least an indication that the gall-bladder may be of service to the economy. Nevertheless the prevailing teaching to-day is in favor of cholecystectomy in many diseases of the biliary passages. In the *American Journal of the Medical Sciences* for April, 1908, Dr. Deaver has taken up the question of cholecystectomy, pro and con, giving in detail the reasons why it should not be performed as frequently as is advocated by many surgeons. He admits that it is indicated in hydrops with obliteration of the cystic duct, in new growths, chronic empyema, gangrene, and perforation of the gall-bladder, yet warns against the removal of the bladder when the cystic duct is not permanently occluded or the walls seriously diseased. He does not believe that cholecystectomy should always be performed in acute suppurative calculous or noncalculous cystitis, while in acute catarrhal calculous or noncalculous cholecystitis he regards it as distinctly contraindicated. He reminds us that drainage is the essential feature in all truly infectious diseases of the biliary passages and that the use of the gall-bladder for this purpose, whenever possible, is safer than the deeper operations, namely drainage of the common duct or hepaticus. When there is a permanent obstruction of the common duct requiring drainage he points out how much easier it is to perform a cholecystoenterostomy than a choledochoenterostomy which would be necessary if the gall-bladder were removed. The remote as well as the immediate mortality from drainage of the gall-bladder is less than that which attends its removal, which fact is offered as another excellent reason for not ablating it. He does not consider the possibility of recurrence of stone an objection to cholecystostomy; this may also happen after cholecystectomy. In all doubtful cases he advises drainage of the gall-bladder rather than removal, even at the expense of getting a mucous fistula.

There is no doubt that while many surgeons agree with Deaver, many of the annual hospital reports and large gall-bladder statistics indicate that cholecystectomy is too frequently performed. Deaver's remarks are gratifying in that they display a tendency toward conservative surgery. He emphasizes that the judicious surgeon should regard nature, should assist her as far as he can, and should therefore not ablate a gall-bladder which is still functionally active or which may later become functionally active. What applies to operations on the gall-bladder applies with equal force to other surgical procedures, and signs are not wanting that the pendulum has reached the limit of its swing toward the operative side of surgery, and that its return movement has begun.

The Physiological Action of Tobacco Smoke.

A great many investigations of this subject have been undertaken, and results have been reported which were widely different in more or less important respects. Usually considerable stress has been laid on the manner in which the combustion of the tobacco was effected, and an important rôle

in the production of the physiological action has been ascribed to the pyridin and allied substances formed as by-products during the process. An unusually painstaking series of observations of this nature is described by Lehmann (*Münchener medizinische Wochenschrift*, April 7, 1908), who comes to the conclusion that, after all, it is the nicotine that gives rise to the well-known effects of smoking, whether it be a cigarette, cigar, or pipe that is used. By one set of experiments it was determined that the carbonic oxide, hydrocyanic acid, and sulphuretted hydrogen of the smoke were inactive under ordinary conditions, and it was then found that of the pyridin, ammonia, and nicotine only the latter was practically important as a toxic substance. The symptoms of acute tobacco smoke poisoning and the amount of nicotine actually absorbed are in accordance with what is known of the toxicology of the alkaloid, and factors which cause a greater amount of nicotine to be absorbed in a given time also increase the symptoms of intoxication. This view has already been expressed, though probably on a less firm experimental basis, and the objection has been made to it that children who smoke the leaves of plants entirely free from nicotine also suffer from symptoms quite similar to those caused by the real weed. Lehmann has analyzed the smoke from such sources and finds that it contains minute quantities of some alkaloid resembling nicotine, which though apparently not toxic for adults, might be sufficiently so to affect children. A point that is left unexplained, however, is why two cigars that chemically have about the same nicotine content may none the less be very different in strength so far as the smoker is concerned, a fact that would seem to indicate that something more than mere nicotine absorption enters into the question.

The Duties of the Physician.

No more noble tribute to the medical profession has perhaps ever been penned than that placed by Robert Louis Stevenson as an introduction to his collection of poems, "Underwoods." It is true that unusual self-abnegation and altruism are required of the really fine practitioner, and as Nothnagel has said, "Only a good man can be a good physician." Another Viennese physician once wrote: "The patient seeks aid which the physician must know how to bring. He must take away the results of the sins of the parents, of ignorance, and of excess. He must alleviate the consequences of poverty, want, and misery, of grief and of despair. The effects of heat and of cold, of the air and the water, of food and occupation, of poison and violence, of contagion, pestilence, and old age, he must ward off and render harmless. He must always stand ready, cheerful, and undismayed, a support to human infirmity, a guardian of life, a source of health and of the highest earthly happiness." In a recent address delivered in Berlin Prof. His quotes the following from a letter which Sonderegger wrote to a friend who asked whether he should have his son study medicine: "There is on earth nothing greater or more beautiful than man, and the study of mankind is the most difficult and exalted subject of thought and action. Human development and ambition, human life and ills, all are in the highest degree remarkable and touching. But you must bring with you keen eyes and acute ears, a great gift for observation, patience, and yet again patience for endless study, a clear, critical mind, and an iron will strengthened by opposition, but yet a warm and tender heart, comprehending and feeling every sorrow; a reverent spirit, and austerity that is superior to sensualities, money, and eminence; furthermore, a decent appearance, polished demeanor, and adroit fingers, health of body and soul; all of these must you possess if you would not be either an incompetent or an unhappy physician. You must stagger under the crushing burden of unending knowledge, and yet preserve the lightheartedness of the poet; you must know all the arts of charlatanism, and yet remain an honest man; once for all, medicine must be your creed and your politics, your happiness and misery. Therefore, advise no one to become a physician. If he still wishes to do so, warn him against it, often and earnestly; but if he persists in spite of all, give him your blessing, if he is worth it, for he will need it!" These words are very flattering, and they are also true as expressing an ideal, and it is right and proper for the physician to strive to be all this and even to hope that he may attain to it in time. But he needs modesty, as well as a reverent spirit and an austerity that is superior to sensuality and riches. There are other professions and callings which demand the exercise of self-denial and patience and sobriety and honesty and all the other virtues; and the physician, when he feels an inclination to contemplate his own goodness, should be careful to preserve his sense of humor, as a help in maintaining a proper balance.

News of the Week.

Warning Against a Possible Swindler.—Dr. A. T. Bristow of Brooklyn writes to warn physicians against a man pretending to be a graduate of Berne, who has obtained one of the writer's cards and is using it as an introduction to other physicians from whom he tries to beg or borrow money.

Darwin Celebrations.—The New York Academy of Science and Columbia University are making plans for a celebration in honor of the one hundredth anniversary of the birth of Charles Darwin to be held on February 12, 1909. As this is also Lincoln's birthday and a public holiday appropriate ceremonies can easily be arranged for. The hundredth anniversary of Darwin's birth and the fiftieth anniversary of the publication of "The Origin of Species" is to be celebrated by Cambridge University on June 22, 23, and 24, 1909.

Child Labor Bill for District of Columbia.—A bill prohibiting child labor in the District of Columbia has been reported to the House by the Committee in the District of Columbia, and it is hoped that this will be taken as a model by States proposing to enact similar measures.

Hospital Saturday and Sunday.—The Distributing committee of the Hospital Saturday and Sunday Association has announced that the total amount collected was $82,452. After deducting the amounts for specially designated hospitals there was a balance of $71,000, which has been apportioned among forty-one different hospitals, on a basis of the amount of free service given by each institution. The Montefiore Home and the Mount Sinai Hospital each receive about $7,000, and St. Luke's Hospital, Lebanon Hospital, Roosevelt Hospital, New York Lying-In Hospital, and Post-Graduate Hospital each between three and four thousand dollars.

McKinley Home to Become a Hospital.—The home of President McKinley, at Canton, Ohio, has been transferred to the diocese of Cleveland and will be converted into a Roman Catholic hospital.

Another Roentgen Ray Sufferer.—The list of those who have suffered serious injury as the result of their devotion to Roentgen ray work has been increased by the case of Mr. Ernest Harnack of the London Hospital. Mr. Harnack has undergone three serious operations in the last six months, two fingers and all the lymphatic glands of the left arm having been removed, as well as three fingers and part of the dorsum of the right hand, so that how far, if at all, he will ever be able to resume his work is doubtful. Dr. Hall-Edwards who is incapacitated as the result of similar injuries has been granted a Civil List pension of £120 a year, and the sum of £1,000 has been collected for him by public subscription.

Cocaine Vender Arrested.—Owing to the fact that the use of cocaine had incapacitated several men at the Norfolk, Va., naval station the matter was taken up by the authorities and evidence has been secured against one of the venders of the drug who has been arrested.

Laboratory Table for Research at High Altitudes.—By the conjoint action of the National Academy of Sciences and of the trustees of the Elizabeth Thompson Science Fund a table has been secured permanently for the use of American investigators desiring to work at the International Scientific Station on Monte Rosa. This station offers facilities for work in physics, meteorology, and physiology, but any appropriate research may be carried on there. Applications for appointment should be addressed to Dr. Charles S. Minot, Harvard Medical School, Boston, Mass.

A Pure and Wholesome Milk Supply for Chicago Babies.—Recently the first step toward giving Chicago babies a pure milk supply was taken by Commissioner of Health Evans. Prominent dairy companies held a conference with the Commissioner, and these suggestions were talked over: A plan by which a special supply of milk from a dairy that is under the strictest supervision might be obtained daily for the babies; a scheme by which a certain number of cows—good milkers—might be brought to Chicago and kept here, their milk to be distributed to the babies each day.

Bubonic Plague.—Flores Ontaneda, a well known scientist of Guayaquil, Ecuador, has died as the result of a laboratory infection with plague bacilli. New cases of the disease are being reported daily in Guayaquil. The despatches from La Guayra, Venezuela, assert that the disease epidemic there is not plague, though the reports are somewhat contradictory.

Reception to Professor Schäfer in Washington.—On April 23, Professor E. A. Schäfer, F.R.S., of the University of Edinburgh, delivered a lecture on "Internal Secretion" before the Medical Society of the George Washington University, Washington, D. C. The lecture was followed by a smoker. On April 22, a dinner in honor of Professor Schäfer was given at the Shoreham Hotel by representative educational and medical men of Washington. Brief speeches of welcome were made by President Needham, George Washington University; President Buell, Georgetown University; Dr. Barchfeld, member of Congress; Surgeon-General Wyman, United States Public Health and Marine-Hospital Service; Dr. White, Superintendent of the Government Hospital for the Insane; Professor Shields, Catholic University of America, and Professor Franz, George Washington University, to which Professor Schäfer fittingly replied.

A Farewell Dinner to Prof. August Martin of Berlin will be given at the Hotel Astor on June 10. Dr. Wm. M. Polk will preside. Tickets at the price of $7 each may be obtained from the treasurer, Dr. H. J. Boldt, 39 East Sixty-first street.

Dr. Richard Mills Pearce, Jr., of Albany has been appointed professor of pathology and director of the laboratory of pathology of the University and Bellevue Hospital Medical College. Dr. Pearce was resident pathologist at the Boston City Hospital, 1896-9; instructor in pathology at Harvard, 1899-1900; demonstrator and later assistant professor of pathology in the University of Pennsylvania, 1900-3, and since 1903 has been director of the Bender Hygienic Laboratory at Albany; director of the bureau of pathology and bacteriology, New York State Department of Health; professor of pathology and bacteriology, Albany Medical College.

Dr. Max Verworn, professor of physiology in the University of Göttingen has been appointed by the Prussian Ministry of Education Kaiser Wilhelm professor at Columbia University for the year 1908-9.

For Another Maternity Hospital.—The Grand Jury has filed a presentment commending the administration of the institutions on Hart's Island and Blackwell's Island. Improvements in some of the buildings are recommended, as well as the erection of another maternity hospital.

Mt. Sinai Hospital.—The George Blumenthal, Jr., fellowship in pathology for the current year has been awarded to Dr. Reuben Ottenberg of New York City.

Association of American Physicians. — The twenty-third annual meeting of this organization will be held in Washington on May 12 and 13, 1908, under the presidency of Dr. James Tyson of Philadelphia.

American Medical Editors' Association.—The annual meeting of this society will be held at Chicago on May 30 and June 1.

American Laryngological Association. — The thirtieth annual congress of this association will be held in Montreal, Canada, May 11, 12, and 13, 1908, under the presidency of Dr. Herbert S. Birkett of Montreal. The secretary and treasurer is Dr. James E. Newcomb, 118 West Sixty-ninth street, New York City.

Kentucky State Association of Railway Surgeons.—This organization will hold its fourth annual meeting in Louisville, May 12 and 13, 1908. The secretary and treasurer is Dr. J. B. Kinnard, of Lancaster, Ky.

The New Jersey Homeopathic Medical Society will meet on May 7 at Princeton, N. J. President Woodrow Wilson of the University will address the society.

Tennessee State Medical Society.—The following officers were elected at the meeting of this organization held in Knoxville on April 16: *President*, Dr. Benjamin D. Bosworth of Knoxville; *Vice-President* for East Tennessee, Dr. C. T. Carroll of Cleveland; *Vice-President* for Middle Tennessee, Dr. J. W. Brandon of Clarksville; *Vice-President* for West Tennessee, Dr. W. T. Blanton of Union

City; *Treasurer,* Dr. W. C. Bilbro of Murfreesboro.

Plymouth District (Mass.) Medical Society.—Officers as follows were elected at the annual meeting of this society held in Brockton on April 15: *President,* Dr. Fred J. Ripley of Brockton; *Vice-President,* Dr. Charles S. Millet of Brockton; *Secretary and Treasurer,* Dr. A. C. Smith of Brockton.

Tolland County (Conn.) Medical Society.—At the one hundred and sixteenth annual meeting of this society held in Rockville on April 21 the following officers were elected: *President,* Dr. James Stretch of Stafford; *Vice-President,* Dr. I. P. Fiske of Coventry; *Secretary and Treasurer,* Dr. E. P. Flint of Rockville.

Rock Island County (Ia.) Medical Society.—The following officers were elected at the meeting of this society held in Davenport on April 14: *President,* Dr. T. J. Lamping of Moline; *First Vice-President,* Dr. W. H. Ludewig of Rock Island; *Second Vice-President,* Dr. M. S. Dondonville of Moline; *Secretary,* Dr. H. L. Youtz of Moline; *Treasurer,* Dr. A. E. Williams of Rock Island.

Hampden District (Mass.) Medical Society.—The annual meeting of this organization was held in Springfield on April 21 and the following were elected as officers: *President,* Dr. George L. Woods of Springfield; *Vice-President,* Dr. C. W. Jackson of Monson; *Secretary and Treasurer,* Dr. R. S. Benner of Springfield.

Death of Professor Schroetter.—Professor Leopold Schroetter, Ritter von Kristelli, died suddenly on April 21 after delivering the inaugural address at the International Congress of Laryngology in Vienna. He was born in Graz in 1837, and had held numerous academic and hospital positions, and was the author of many books and papers, mainly on laryngological subjects. He was in attendance on Emperor Frederick at the time of his death.

Obituary Notes.—Dr. Charles J. Towne of Essex, Mass., died on April 15 at the age of sixty-seven years. He was born in Stoddard, N. H., and received his medical education at Dartmouth. He first practised in Richmond, N. H., but four years later removed to Townsend, Mass., where he remained until about thirty years ago, when he came to Essex.

Dr. A. G. Oyen of Petoskey, Mich., died on April 18 at the age of fifty-seven years. He was born in Macon, Mich., and in 1883 received his medical degree from the University of Michigan. He had practised in Petoskey for twenty-two years.

Dr. Henry T. Legler of Oakland, Cal., died at an advanced age on April 15. He was born in Dresden, Germany, but early came to this country and had practised in California for many years. For ten years he was County Physician of Alameda County.

Dr. Ezekiel Morrill of Concord, N. H., died on April 18 at the age of seventy-one years. He was born in Chester, Ohio, and received his medical education at the Castleton Medical School and the Cleveland, Ohio, Homeopathic Medical School. He served as surgeon in a New Hampshire regiment during the Civil War, and then practised for a time in Salem, Mass. He removed to Concord in 1874, and was elected to the New Hampshire Legislature in 1905.

Dr. Edward Dowd, recently of Babylon, L. I., and also of Winnetoon, Neb., died on April 27 at Danville, N. Y. He was a graduate of the University of Iowa Medical Department.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth concisely the nature of the ailments therein described with remarks on their appropriate treatment.

————, Louisiana.
January 18, 1908.

Dear Doctor:

To-day I went to see Dr. ———, who has always been our physician, to ask what I should do to get relief from a distressing symptom that has fastened itself upon me during the past year, and he advised me to consult you. Before making the journey to New York I should like to give you a brief outline of my infirmity and to ask you what hope you can hold out to me that I shall again be well and happy. I say it is during the past year that the most disagreeable symptom has come, but in reality I have had symptoms for a longer period than that. It is only latterly that it has begun to interfere with my work and to menace my joy of life. It is difficult for me to describe my condition: While I am at work in my study, intent (though perhaps not wholly) upon some problem that interests me, my breathing seems to stop. The more I concentrate my attention the greater is the disturbance of respiration and this, of course, distracts me. I try to push it out of my mind, as it were, and to get down to the matter before me, but, as soon as I succeed in doing so, my breathing hitches or stops. I then begin to experience a sensation of nervousness and obscure apprehension and I have to give over my occupation and go out-of-doors or get diverted in some way. There seem to be variations of the disturbance of breathing. For instance, I want to know the time; I look at my watch but before I am sure of the exact time, *i. e.* while I am coming to a conclusion, the breathing seems to stop. While reading I am often nervous and I have to practice breathing in a sort of surreptitious way in order to read. While drinking water I have to stop at the end of a swallow and then start again.

Then I have difficulty in making up my mind or at least in convincing myself that I have done certain acts. After writing a letter and having addressed the envelope, I will look many times before being convinced that I have signed and addressed it properly. I lock the door and then am not satisfied that it is fast; and the same thing is true of the windows. The minute that my hand leaves the door or fastening I am assailed with doubt.

I have always thought this was a species of nervousness; now it is associated with fear, want of confidence, lack of certainty, and mind wandering. When I have done something I am not sure of it, and the effort to make sure of it disconcerts me thoroughly. The fear not to use the right foot when starting and when going in and out of doors, and of not giving and receiving things with the right hand annoys me a great deal. I argue with myself and convince myself that it is "Miss" and not "Mrs." but as soon as I have apparently convinced myself the conviction deserts me and I must begin anew. After I have put the letter in the envelope I have to take it out and replace it time and time again before I am sure that it is in proper form, and after it is stamped and sealed and in the mail-box, I am worried to know whether it is properly stamped and sealed, and I have had to wait for an hour or more until the collector came to open the box.

I am very much bothered and worried at times

to know whether the paper on which I write is free from having been written on before, and I turn the paper on which I am writing over and over before I am convinced. Superstition as to time, things, minutes, and days, extreme conscientiousness as to exactness in every detail worries and perturbs me. When I start off with my right foot, though I see the moving of the foot I have no consciousness that the foot has moved, the act is finished while the mind is in doubt. When I am giving things out of the right hand, as soon as the thing is given the act is doubtful and I want the act repeated, though the repeating might not be more impressive.

I am afraid you will think I am crazy, and indeed, I often ask myself if it is not true that I am losing my mind. Apparently I am in possession of my faculties and my conduct is in conformity with such possession. Only a few persons know anything about my affliction, and I nurse the hope that I can, with the aid of your skill, rid myself of it without notoriety.

I suppose I should tell you something about myself before I proceed further to describe my complaint. I am 29 years old, unmarried, and a clergyman of the Presbyterian church. I do not officiate in this capacity for I hold the position of Assistant professor of history in ——— University, to which I was appointed after I finished my graduate work in that institution four years ago. I am fairly successful as a teacher when my health permits me to discharge my duties, but last autumn I was obliged to ask for leave of absence and come here to my former home to see if I could pull myself together.

This complaint that I have has been developing for some time. I can see now that certain feelings, doubts, and compulsory notions that I had as a youth were really forerunners of many of the symptoms that I have nowadays. As a boy I was sensitive, shy, and retiring, at least apparently shy and retiring. In reality I was not shy, for when in the presence of intimates only, I could assert myself. I was not very popular at school save with a few, but I believe now this was because of a certain preciosity which I looked for in others and which I am now glad to believe is uncommon. I was a pious boy and walked in the fear of the Lord. Indeed, one of my first worries was whether or not I had an adequate awe of the Lord. Another was what might happen to me if I told a lie. This latter led to a literalness of speech that gave me the reputation of being affected and pedantic. I blush now thinking of the period when I felt obliged to conform to the Biblical injunction that verbal intercourse should be limited to yea and nay. But these were only passing fancies as were so many others that I had, and which I suppose are common to an emotional, high-strung youth. Meanwhile I had a facility for learning which often gave rise to favorable comment. It must have been about my fifteenth year that I began to worry about nocturnal emissions. I didn't know what they meant and I was afraid to ask, as I believed they were peculiar to myself and in some way connected with personal inadequacy or insufficiency. I think now that the feeling I had was one of shame more than anything else, for I recall distinctly that I was very much embarrassed by and ashamed of the hair that had grown on different parts of my body, and I got myself very much wrought up considering what would happen if anyone found out about it. I was always inclined to blame myself for anything that happened that I didn't understand. Perhaps I should convey my meaning better were I to say that I was self-deprecatory, yet I was by no means unappreciative of my ability to do things, nor did I falsely estimate my judgments, but some way or another, when anything happened to cause a disagreeable feeling tone, as it were, I felt that it would not have happened, if I had been like other persons.

About this time, *i. e.* when I was about 16 years old, I got very much concerned about the meaning of things which everyone takes for granted, such as why do two and two make four, why do things look real, and so on through a long list of interrogations. I can't begin to tell you of all the silly ideas that came into my head and kept me from having that joy of youth and health which my companions had. I think, however, that if my parents had had any notion of what was going on in my mind they would have seen that what I needed most was to stop trying to solve the riddle of existence, and to try to live without questioning. I am willing to do that now, and I have disciplined myself to stop being an interrogation point. I wish my father had either sent me off to school or made me do all sorts of things that would have developed within me a taste for sport or athletics. But he was absorbed in an invention which he was trying to perfect and which would revolutionize the cotton business, and apparently had little time for his family. My father was rated a brilliant man and the reason why he did not win out was that he was not "practical."

While I was in college I seemed to have got rid of my vagaries and I look back upon that period as one of great happiness. I formed some intimate friendships and many pleasant personal relationships, and it was with the greatest satisfaction that I saw the roadway of life leading back to ——— (the University town), after I had taken orders. But now I am in despair. You can have no idea of how incompetent I feel to throw off the trammels of this incubus that has fastened itself upon me. It is useless to tell me to learn to think straight, to use my will-power, to divert myself. I have done all this with my whole strength and I am no better. In fact, here I am apparently in perfect health, and to all intents and purposes of sound mind, yet incapacitated.

"My fortune standing in the precipice
'Tis counsel that I want and honest aids."

Yours truly,

——— ———.

P. S.—It has occurred to me that I should try some sort of mind cure. What do you think of it? Do you think I can look forward with any confidence that I shall get well? You know "the miserable have no other medicine but only hope." ———.

New York, February 12, 1908.

Dear Sir:

In reply to your letter of the 18th inst., I am in somewhat of a quandary whether I shall tell you the name that we physicians give to the disorder from which you suffer, or whether I shall endeavor to put before you certain rules of life and conduct, conformation to which may restore you to a life of usefulness and comparative happiness. If I do the first, you may be led to look up the writings upon the subject, and applying the statements to be found therein to yourself, to take a distorted view of your disorder, and possibly reach the conclusion that the way out of the wilderness is so intricate and obscure that you will not come safely to the end. You know, I am sure, that few things

warp our judgment so much as illness, and especially illness within the mental sphere. There is a custom that few physicians transgress, and that is not to undertake to treat themselves when they are ill—it matters not the nature of the ailment. The physician whose training and life-habit it is to deal with disease, finds that this is the safest and most expeditious course to pursue in order to regain health, and it is probable that the layman can safely follow his lead. I shall therefore be very frank with you in the discussion of your infirmities, and endeavor to put before you the nature of your disorder in such a way that you will comprehend it. Nothing aids the physician so much in his fight with disease as intimate acquaintanceship and full understanding of the nature of the disease, and when he comes to deal with a disorder whose cure requires not only the cooperation of the patient but also his most intelligent initiation and aid, it is of the greatest value that the patient should have a fairly clear conception of it as well.

The symptoms which you describe have probably been known to physicians since the beginning of medicine as a practice and as a science; not that we find them mentioned in medical literature of the ancients, but because we frequently read in the biographies of men whose names have become more or less immortal, of many of the symptoms that you describe. Men and women of genius, men and women who write their names indelibly upon the scroll of time, are usually individuals of nervous temperament, of neurotic constitution, of neuropathic diathesis, and although it is in spite of and not by virtue of this that they achieve fame and add to the luster of their times and to the welfare of the world, nevertheless it would seem that the greatness of their endowment nearly always carries with it the drawbacks of such a temperament. I do not by any means intend to convey the idea that men of genius need necessarily have symptoms such as those that you relate; fortunately for them and for us,—as inhibition is never the strong point of genius,—they do not.

It is only latterly, however, that physicians have realized that symptoms such as those that you relate are the expression of a neuropathic diathesis or constitution which has not been properly disciplined, by hygienic measures, that is to say which has not been developed toward a normal condition by the most approved modes of treatment during the formative years of the individual's life. During the past few years much study and attempt at interpretation has been made of these symptoms, with the result that following the lead of a French physician, Janet, many of us look upon these symptoms as indicative of an hereditary, constitutional, idiopathic (meaning thereby one that develops without apparent antecedent cause) disorder of the nervous system. When I use the word nervous system in this sense I mean the entire nervous organism, a large part of which is made up of the brain. Therefore it is called a psychoneurosis and to this psychoneurosis the name Psychasthenia is given. The name is not particularly appropriate, as it indicates only that there is a weakness of the mind. One reason why it has seemed the more appropriate perhaps is that neurasthenia, which indicates a weakened or exhausted condition of the nervous system, has found its way into everyday speech and conveys a more or less definite meaning. In fact, the advent of the term psychasthenia has had much to do with narrowing our conception of neurasthenia and making the condition to which it is applied a well-defined one.

You will gather from what I have said that psychasthenia is like the poets,—born, not made. It is quite likely that anyone may develop certain definite fears, some obsessions, stereotyped modes of worry, of doubting, of questioning, etc., the possession of which does not necessarily mean that the individual has psychasthenia, but an individual whose usefulness becomes impaired by a group of mental and emotional symptoms made up of obsessions, imperative concepts, fears, doubts, anguish, compulsory movements, enfeebled will-power and disturbed peace of mind and who develops these symptoms comparatively early in life without adequate cause, and who, like yourself, has his vocation disturbed and his career seriously threatened, may legitimately be said to have psychasthenia. But you ask, "Why should I have it and from whence does it come?" You have not outraged any of Nature's laws, you have not been so unfortunate as to encounter accidentally any of the salient factors from which disease flows. Psychasthenia comes like your birth—without your will and without your leave. It, like a few other constitutional disorders of degeneracy, such as migraine, hysteria, and epilepsy is but a manifestation of a disturbance in the great synthesis that goes to make the individual. In other words it is an evolutionary defect.

The problem that we neurologists most frequently have to confront, is how to arrange the life of the burdened individual who consults us, so that his career shall not be a failure and the sum-total of happiness which should be his shall not be curtailed. Unfortunately, we do not get the individual, as a rule, until very late in the day, until after he has fully matured and is a creature of fixed habit. We are in the position of a skilled watchmaker who has been handed a chronometer of which every part seems to be perfect, but still it will not do the work for which it was intended, or, at least if it does the work, it proves erratic and unreliable. The watchmaker gives very little satisfaction if he says that a certain bit of steel used in the construction was not adequately tempered, or a certain coiled spring was not properly annealed, he must do something that will make the watch keep time reliably and in order to accomplish this he must almost always attack it fundamentally; he must take it to pieces and proceed from the very foundation. A somewhat similar course must be pursued by the physician who essays to treat such constitutional disorders as psychasthenia. He must attack the individual fundamentally; he must dissect his character; ferret out the primordial origins of his false-beliefs, analyze the remote antecedents of his first obsessions, go back to the early times when it was admitted that effect naturally followed cause, and perhaps more important than all, try to put clearly before the individual examples of real humility and show him his own inconsequentiality. He must convince himself that there are certain unavoidable things in the world which everyone of a neurotic, emotional temperament finds disagreeable, but that in reality they make very little difference to any one save the individual himself, and that the safest and surest thing for him to do is to cultivate the habit of indifference towards them. In other words you must get yourself and the world, or your environment in the right perspective. Except to a few, you are of no importance whatsoever. You must realize that save to the few persons that constitute your family, your welfare does not concern anyone. Treat yourself if you can as the world treats you, as too commonplace to be noticed!

Adopt this attitude towards your symptoms, or if you must attack them one after the other, consider that you run the risk of accentuating them by giving them too much consideration. To be be quite normal one must emulate the young child or the animal and be unselfconscious. You know there was a time when even the germs of these distressing ideas and sensations that you now have did not exist. Therefore, endeavor to determine what their antecedents were, and having found them treat them as an enemy; have no commerce with them save to effect a truce. It is largely a matter of self-cure, particularly for a man who like yourself has the dual advantage of intelligence and a trained mind. You will be assisted in the matter by a course of appropriate reading, carefully selected and faithfully carried out. An adequate philosophy is, in reality, what you are in search of, and I should recommend to you a careful study of Aristotle and Epicurus. You can find amongst the writings of the latter this statement: "We should not be hampered by foolish fears from attaining the goal of our existence—happiness. Pleasure is the highest good; not the pleasure accompanying a passing sensation, but pleasure as a permanent state,—that state of deep peace and perfect contentment in which we feel secure against the storms of life. The pleasures of the mind are preferable to voluptuousness, for they endure; while sensations vanish away like the moment which procures them for us. We should avoid excess in everything, lest it engender its opposite, the permanent pain resulting from exhaustion." You will, I am sure, find the teachings of this philosopher, if approached in the right spirit, of the greatest comfort to you.

If you can take the point of view that Aristotle took, that the mind does not originally possess ready-made ideas but the faculty of forming them, it will help you very much in getting rid of these obsessions that have fastened themselves upon you like barnacles on the bottom of a boat.

What shall you do directly to help yourself? You must make a firm resolution that you will at certain times in the day dislodge them from your mind by force of will alone and each time make the dislodgment complete. A repetition of this will make for the ease with which they are successfully dissociated and the length of time which they remain away. You will find, moreover, the greatest help from translating your thoughts into some form of action, *i. e.* of not bottling up your thoughts and turning them over and over in your mind. In other words, if you are able to display your thoughts in speech, in efforts for the benefit of others, in anything that has a definite purpose, in sport, etc., it will be of advantage to you.

You have no doubt heard of cures that have been made by Christian Science and other modes of supernatural healing. It is in cases such as yours in which simultaneous bolstering of the will-power and obscuration of the Ego is required that they often accomplish more than we physicians are able to do. You will undoubtedly have suggested to yourself that there is a port of safety for you in the harbor of that cult, and I shall say nothing to you to discourage you from turning your sail in that direction if you can reconcile an espousal of the most nebulous and mystic parts of neoplatonism with your intelligence. I deem it fitting, however, to warn you against the rival camp which is now putting forward claims for recognition as a hygienic force. You have no doubt heard of an effort on the part of some Churchmen to combine the treatment of disease with their own legitimate work, that of public ministration in the Christian Church. There is nothing new under the sun! Nearly 800 years ago the Church and the practice of medicine were forcibly rent asunder by the first Lateran Council during the pontificate of Calixtus II. Things had reached such a pass that even the Twelfth Century wouldn't stand it. Though in this modern instance the advocates cannot be accused of "Ordinis sui propositum nullatenus attendentes pro detestanda pecunia sanitatem pollicentes," they claim to do that which they maintain that honest men of ability backed by the training of a lifetime cannot do, and they gratuitously assume that "if medical science is to regain the esteem of the world, it must take the ground that for the great majority of the ailments that afflict American humanity, the contents of the pharmacopœia are of very limited efficacy, that for these the directly curative agencies must be moral and psychical." The only agencies that they call to their aid are: Suggestion, Subconsciousness, which is especially amenable to control from without, Faith, and Prayer. So far as I can see, the only one of these that is not in hourly use by the physician is the last. It must be a much more efficacious agency than is generally believed if it alone accomplishes all that the Emmanuel Church movement advocates say that it does, for surely, being clergymen and not physicians, without natural predilection and without special training they cannot use the tools of our profession more skillfully than we can ourselves. Yet despite the poverty of their therapeutic resources their cures read like the testimonials that set forth the efficacies of "Father James' Medicine" and "Barnum's Safe Spleen Cure." About 70 per cent. of alcoholism, says their reverend spokesman in a recent magazine article, is amenable to suggestive treatment—Credulity where is thy limit? Gullibility where is thy confine?

Christian Science represents an attempt at revival of the emanistic pantheism which was the fundamental conception of Neo-platonism. The Emmanuel Church movement represents an attempt at revival of a custom of the dark ages. I hold no brief for the members of my profession in this matter, but I have no hesitation in saying to you that it is purely a gratuitous assumption on the part of the reverend director of the Class for the Moral Treatment of Nervous Disorders, Boston, that medical science has lost the esteem of the world. This assumption is just as true and no truer than the statement that the "effort is scientific" (meaning the Emmanuel Church movement), or that "the movement is an attempt to weld into alliance the most progressive neurological knowledge and a primitive New Testament Christianity." If any such attempt is being made no evidence of it has been brought forth. As a matter of fact, the science of medicine and the art of therapeutics are to-day the envy and the wonder of the world. Once we conquer cancer and find an antidote for alcohol, we will know just how Alexander felt immediately before the sudden gush of tears that has become so famous. You might think from the lucubrations of the supernaturalists that the world is not only filled with folly and sin but with psychasthenia, incipient insanities, simulated epilepsy, hypochondria, anemic headaches, functional insomnia (whatever that may mean), melancholia, to enumerate only a few of the Christianity and Health Series. But as a matter of fact, as soon as our hospital train passes the psychoneurogenetic belt of

Boston and Chelsea in its journey out to meet the ailing and infirm people of the United States, these maladies and all the others which he mentions, but which I haven't copied, play comparatively a small part. Perhaps I have no justification in making this remark, having had only twenty-five years' experience with nervous and mental disease gathered from all over the country, and no experience whatever in clerical matters.

Our stay in this vale of tears is but a preparation for the life above, unmeasured by the flight of years, and the amount of preparation needed by us is so great that I believe your cloth hasn't time to practise medicine. The truth of the matter is that a man like you should no more need an outsider's help to overcome his symptoms than he would to cure him of swearing or of boasting, of a belief in ghosts, or in spiritualism. You wouldn't send for a surgeon if, having a thin skin, you got a sliver in your finger. You would set to work to remove it yourself, and in nine instances out of ten, you would succeed. You may be sorry for yourself because you have a thin skin, but you soon learn to take precautions not to injure it. You need to look back and discover the beginnings of your various doubts, fears, obsessions, and aboulias, and root them up one by one. If you can't get the right perspective, come to see me. I advise you to return to your work. The disciplinary plan of treatment which I want you to go through can be done just as well, if not better, while you are at work than when you are idle, and it is always wise to regain your equilibrium in the atmosphere and environment in which you are going to live. Possibly when I see you I shall have something to say of certain physical measures, such as exercise, bathing, occupation, play, diversion, and their relation to mental and emotional equanimity, but as you say nothing about your bodily health in your letter, I shall hold these in reserve.

Yours very sincerely,

P. S.—Have you ever read the life of a first-class hypochondriac like Carlyle, or of a typical neuropath like Flaubert? It might be an excellent thing for you to do.

Correspondence.

THE OPTOMETRY BILL.

AN APPEAL TO THE MEDICAL PROFESSION OF NEW YORK STATE.

To the Editor of The Medical Record:

Sir:—The Legislature has passed a bill creating a profession of optometrists, and it is up to the Governor to sign or not to sign as the merits of the case appeal to him.

The bill, which is Senate Bill No. 1033, creates a board of examiners of "five persons who shall possess sufficient knowledge of theoretical and practical optics to practise optometry and who shall have been residents of the State actually engaged in the practice of optometry for at least five years." It provides that any person who has been engaged in the practice of optometry for two years next prior to the passage of the act, may receive a license without examination, upon recommendation of the board of examiners.

This bill is an invasion of the sphere of medicine in one of its most important branches, and confers privileges on certain people, which, in accordance with the wording of the act, they are utterly incompetent to exercise. The bill grants to opticians the right to adjust lenses to people's eyes in need thereof, and denies them the right to use drugs. Without the use of drugs, in certain cases, even the most competent physicians cannot properly adjust lenses to the eyes, especially in children, and great harm can be produced by attempting such practice without using drugs. The knowledge of optics alone, however extensive, does not render a person competent to do the work this bill would give opticians the right to do. To examine the eyes and adjust lenses one should have a knowledge of anatomy and physiology at least, but this bill provides only for a knowledge of optics. The many diseased conditions which may influence the eyes and vision are not considered at all. The ability to make a diagnosis is necessary to enable one to discriminate between visual defects due to diseases, and those due solely to optical errors, both of which often exist at the same time, and this ability requires more than a knowledge of optics. The passage of this act denotes gross and inexcusable ignorance on the part of members of the Legislature, or an utter disregard of the welfare of the community.

It is a most vicious type of special legislation in that it permits an examining board of five members to discriminate between opticians who apply for certificates of exemption. The recommendation of this board is necessary before these certificates can be granted, and this board can limit its recommendations to a chosen few. If the physicians of this State will go on record with the Governor, opposing this bill, it will never become a law, and it is hoped that they write at once, urging the Governor to withhold his approval.

Frank Van Fleet, M.D.,
Chairman Committee on Legislation, Medical Society of the State of New York.

Walter E. Lambert, M.D.,
Member Committee on Legislation, Medical Society of the County of New York.

THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(Special Report to the Medical Record.)

TRYPANOSOMIASIS—SANITARY WORK IN HONGKONG—POISONOUS SNAKES IN JAPAN—INOCULATION OF BACTERIAL VACCINES—THE LIVER IN SCHISTOSOMIASIS—JELLYFISH STINGS—OIDIOMYCOSIS—ANIMAL PARASITES OF MAN—AUTOPSIES AT THE PHILIPPINE MEDICAL SCHOOL—INFANTILE BERIBERI—CAUSES OF THE REAPPEARANCES OF CHOLERA—DIFFERENCES IN THE STRAINS OF CHOLERA MICROORGANISMS.

Manila, P. I., February 28, 1908.

The first scientific session of the fifth annual meeting of the Philippine Islands Medical Association took place at 3 P. M., February 27, in the lecture room of the Philippine Medical School.

The actual work of the fifth annual meeting of the Philippine Islands Medical Association was opened by a clinic at the Army Division Hospital, which was given by the staff of that institution for the visiting delegates and members of the association. The clinic, which proved to be most instructive, was begun by an operation for abscess of the liver by Captain and Assistant Surgeon Thomas L. Rhoades. Unfortunately, however, the abscess could not be located, so that the operation was rather an exploratory one. The patients in the medical ward were then visited. A large number of cases of the various forms of intestinal infection were shown, more especially cases of amebiasis, bacillary dysentery, and uncinariasis. A particularly interesting feature was the demonstration of hook worms in jars partially filled with wet sand. Dr. Ruffner, who was in charge of the ward, stated that they had returned to the ipecac treatment for dysentery and had very successful results with the same. He administers a medium dose of opium, which is followed within a few hours by a maximum dose of one of the preparations of ipecac. This treatment is repeated as often as may be necessary. Dr. Whitmore showed a number of cases in which bacterial vaccine had been used with marked success, more especially cases of gonorrheal rheumatism.

The first paper, entitled "Human Trypanosomiasis in the Philippine Islands: First Reported Case," by F. H. Willyoung, from the Biological Laboratory, Bureau of Science, was read by title only. Mr. Willyoung had observed these trypanosomes in one of the slides which were taken primarily for the purpose of making diagnoses of leprosy. The particular slide in question, however, was not examined until he returned to the laboratory, where he noticed these trypanosomes, which were later tentatively diagnosed as *Trypanosoma gambiense*. At the time of the meeting Mr. Willyoung was in the provinces endeavoring to find the particular person from whom the specimens were taken in order that the same might be verified.

The next number on the program was a brief address by Dr. Francis Clark, Medical Officer of Health and delegate from His Britannic Majesty's Colony of Hong-

kong, in which he gave a brief outline of the sanitary work in Hongkong. He stated that they were combating plague now upon the theory that it is only conveyed by the means of rats and rat fleas, but that up to the present time they had been unable completely to eradicate this disease from Hongkong. He attributed the failure principally to the fact that some 4,000 or 5,000 persons travel daily between Canton and Hongkong, and as Canton is well known as one of the most insanitary places in the world, where practically all the major communicable diseases are encountered at all times, the direct result is that Hongkong is continually infected from that city. He related one instance in which plague occurred in a five-story building in a room in which, upon investigation, was shown to be the only one in the building in which the grating from the drain pipes had been removed and which in all probability had admitted infected rats into the apartment.

His remarks with regard to the disposition of night soil were particularly interesting in view of the fact that the removal of this refuse, instead of being a source of outlay to Hongkong, is a source of great revenue, being let by contract to the highest bidder, and brings as much as $70,000 ($35,000 United States currency) annually. Contrary to the general belief, Dr. Clark stated that this night soil is not used for the purpose of fertilizing vegetables, but is put into pits in the country districts, where it remains for six months or more, after which it is used for fertilizing mulberry trees, and, of course, there is no objection to this, because nothing edible is taken from the trees.

The next paper was read by Professor Taichi Kitajima, M.D., Infectious Diseases Institute, delegate from His Imperial Japanese Majesty's government, entitled "Poisonous Snakes in Japan." He stated that snake bite was treated by making a serum for the respective snakes by the same method as is used by Yersin in making anti-snake venom for cobra and other snakes in India.

The next paper, entitled "The Inoculation of Bacterial Vaccines as a Practical Method for the Treatment of Bacterial Diseases, with Special Reference to Infections with the Gonococcus," was read by Dr. E. R. Whitmore, Captain and Assistant Surgeon, United States Army. Dr. Whitmore's paper was of particular value, because he had previously shown his cases at the First Reserve Hospital, upon which he had used bacterial vaccine, and which showed most conclusively the excellent results which may be obtained by this method. He gave histories of a number of cases of furunculosis, and gonorrheal arthritis in which he had used the vaccine with excellent results. One of the most striking cases which he cited was that of a case of gonorrheal arthritis, which had been treated in the First Reserve Hospital for more than three months with all the therapeutic measures which are ordinarily recommended for this disease, but without effect. Dr. Whitmore then injected vaccine made from the patient's gonococci, and in less than twenty-four hours he showed marked symptoms of improvement, and was entirely free from pain, and had the first comfortable night he had had in many weeks previous. The second day the patient expressed himself willing to return to duty, and he was actually discharged within ten days from the time the treatment was given him.

The next paper read was that by Captain J. M. Phalen, Assistant Surgeon, United States Army, entitled "Notes on the Condition of the Liver in Schistosomiasis." He reported one case which was admitted to the Division Hospital January 16, 1908, and died the following day. An autopsy was performed three hours after death, but no macroscopical alterations were detected in any of the organs, with the exception of the liver and spleen, which were found to be moderately enlarged, the latter being somewhat adherent. The liver presented pale patches over its surfaces and minute whitish nodules which varied in size from a mere point up to the size of the head of a pin. On excising and crushing these nodules oval eggs were found measuring approximately 70 by 40 microns. Sections were stained with hematoxylin and eosin and with Bismarck brown, and upon examination were found to stain deepest in the center, which was composed of an indefinite mass of nuclei, red blood cells, and fibrin. These nodules were apparently walled off from the rest of the liver structure by connective tissue capsules. He stated that the difference in pathology between *Schistosomum japonicum* and *Schistosomum hematobium* depended upon the location of the parasites; the one in the venous and the other in the arterial side of the portal circulation, and, second, on the morphological difference in the ova.

The next paper was that by Dr. E. H. H. Old, Assistant Surgeon, United States Navy, entitled "Observations on a Series of Cases of Stinging by Jellyfish." Dr. Old reported nine cases which within half an hour after the persons were stung by the jellyfish, were affected with cough, serous expectoration, and in some cases this was slightly tinged with blood. The place at which the sting took place was generally a slightly raised and visculated, red area, which "wept." There were severe pains in the back and at the point at which the stinging took place. The patients also complained of nausea, and in some instances showed hysterical symptoms. Apparently a short rest in bed with some palliative treatment resulted in recovery. He reported one case in which death occurred within three hours after being stung.

The second scientific session was held at 10 A. M., on the morning of February 28. The first paper, entitled "Oidiomycosis in the Philippines," was read by Dr. Henry J. Nichols, Assistant Surgeon, United States Army. He stated that considerable attention has recently been directed to the group of diseases caused by closely related fungi, the life history of which resembles that of protozoa. This group includes local and generalized blastomycosis and coccidioidal granuloma. A comparison of the organisms isolated for this purpose lead Ricketts to conclude that they were all species of one genus, for which the general term oidiomycosis was suggested. He stated that blastomycotic infection of animals and man and possibly a coccidioidal infection in man were present in the Philippines. According to local veterinarians blastomycosis was specially prevalent during the years 1901 to 1903, when many horses were killed on the supposition of the presence of true glanders. He stated that Strong had found a case in a native and that Shattuck had noticed two cases out of thirty-four ulcers examined and that the last Army Board on Tropical Diseases had reported a case in a quartermaster's employee which was of two years' duration. The lesions occurred on the face and somewhat resembled ringworm. He reported one case of an obscure lung infection. The patient is an American, an enlisted man in the army, who, in the year 1899, while in the Philippines, developed an elevated sore on his left shin, which he attributed to wading in the rice paddies. The sore gave him considerable trouble and he went into the hospital, where he was treated for about six weeks, the sore being cauterized with carbolic acid and finally healed. Six months later he had an attack of chills and fever with cough and expectoration, and has never been entirely well since. He enjoys good health for a few months and then suffers a month or two from fever with pains in the chest and expectoration. An examination of the sputum was made and found to be blood streaked. Examinations for tubercle bacilli were invariably negative, as well as inoculations into a guinea pig. The blood was examined for malarial parasites with negative results. The sputum on sedimentation showed numerous round bodies from 20 to 30 microns in diameter, which were surrounded by thin capsules. They were easily distinguished from myelin granules or mucous or fat globules. A monkey was inoculated in the peritoneum, and after a month was chloroformed, and a fluctuating nodule about the size of an egg was found on the abdominal wall and adherent to the intestine. The pus contained many large cells filled with small round bodies not eosinophilic. Several subsequent inoculations of guinea pigs and monkeys showed the same bodies. This fungus has separate mycelia and aereal hyphæ and grows rapidly on glycerin or glucose agar and potato, but very slowly on ordinary agar. In bouillon a flocculent mass forms at the bottom of the tube. Sugars are not fermented. In these respects it conforms closely to the description of cultures of coccidioidal granuloma. The only difference is the production of green, yellow, and brown pigment on glycerin agar. One of the striking features of the pus from these inoculations has been the presence of raylike structures. The similarity of these rays to those of actinomycosis has been mentioned by Montgomery and Wolbach.

The next paper read was that of Dr. Philip E. Garrison, Assistant Surgeon, United States Navy, and Assistant Professor of Tropical Medicine, Philippine Medical School, entitled "The Prevalence and Distribution of the Animal Parasites of Man in the Philippines, with a Consideration of Their Medical and Economic Importance." Dr. Garrison gave a statistical summary of the parasites which were most numerous in the Philippines and showed that among the prisoners of Bilibid some 4,000 in number, were examined, and over 60 per cent. were found to be infected with one or more parasites, the commonest infection being with the ankylostoma, and he invited particular attention to the excellent results which had been obtained in reducing the general mortality and morbidity of the prisoners by treating all the infected persons for their parasites, the death rate being reduced from 60 to 15 per thousand.

The next paper was "A Report on the First One Hundred Autopsies at the Philippine Medical School," by Dr. Philip A. Gilman of the Philippine Medical School. Dr. Gilman's report was particularly valuable in that it showed

that over 50 per cent. of the victims showed well-marked signs of tuberculosis, and that more than 30 per cent. were found to have lesions of amebic dysentery. This latter fact was particularly interesting because it has heretofore been generally believed that the natives did not suffer to any extent from amebæ, but from the figures given in his paper it would seem that they are probably as much affected as the white men.

The next paper read was entitled "A Case of Infantile Beriberi, with Autopsy Report," by Dr. José Albert, Professor of Pediatrics, Philippine Medical School. The patient in question was three months of age and was one of the first that has been authentically reported from the Philippine Islands.

The next paper on the program was a brief address by Dr. Cheng Hao, delegate from His Imperial Chinese Majesty's government. He stated that China was at last beginning to adopt many of the sanitary measures which had been found so useful in other countries, and that in the next ten years considerable progress in this direction might be looked for in the Celestial Empire.

The next paper was that entitled "Some Considerations with Regard to the Cause of the Frequent Reappearance of Cholera in the Philippine Islands, with Statistics Beginning with the Outbreak in 1902 to January 1, 1908," by Victor G. Heiser, M.D., Director of Health for the Philippine Islands, Chief Quarantine Officer and Passed Assistant Surgeon, United States Public Health and Marine Hospital Service. Dr. Heiser stated that at first sight it would appear that by the diffusion among the masses of the plain, simple fact that cholera can be contracted only by introduction into the mouth of contaminated food or drink, the disease should have been eradicated from the Philippine Islands before this time; but he invited attention to the fact that the climate is favorable for the development of the cholera organism throughout the four seasons of the year; that the mass of the population are ignorant and inaccessible, and that much superstition exists; that one of the most popular beliefs is that boiled water is injurious; that the habit of eating large quantities of uncooked food with the fingers is almost universal; that on account of over 60 per cent. being inflicted with intestinal parasites it is shown that they are very liable to contract any other intestinal disease with which they may come in contact; that the people are physically weak and unresistant; that practically all the drinking water is obtained from shallow surface wells, from which it may be seen that the disappearance of cholera up to the present time could scarcely be hoped for. The main object of the paper, however, was to account for the reappearance of the disease several months after it had apparently completely disappeared. He stated that at least three outbreaks, viz., those of August, 1905, June, 1906, and August, 1907, were regularly preceded by suspicious deaths in which the symptoms closely resembled those of cholera, but in which the cholera organism could not be demonstrated, but that each succeeding case became more and more typical, both clinically and at autopsy, until finally the cholera organism could be demonstrated in the intestinal discharges. He stated that the outbreaks in the provinces of the Philippines seemed to be invariably traced to Manila, but that the cases occurring in Manila were not traceable to an outside source, in consequence of which it would appear that the disease must originate in this city. In view of the fact that the cholera organism so far as is known is only capable of being propagated in a wet medium, the only place in which it could exist would be the city water supply or in the city sewer system. In view of the limited number of cases occurring in the city of Manila, the city water supply may be dismissed from consideration, and it would appear that the sewer is the only place in which a constant wet medium could be had throughout the year. With this object in view, examinations were made of the city sewers and cholera organisms were detected in them. This led to the following hypothesis:

That the cholera organism is continuously present in some form in the sewer system of Manila; that at certain stages of its atypical form by passage through the human intestine or otherwise, it first is capable of producing a disease resembling cholera, but the organism cannot be recognized by the present laboratory methods; that successive passages through the human intestine produces a typical cholera vibrio; that possibly the disease disappears owing to the population gradually becoming immune by eating fish and other sea products which have been taken from cholera-infected waters, or drinking the water itself, all of which contain cholera organisms or their products which become attenuated by the treatment which such food products receive. An immunity of this kind appears probable from the fact that cholera organisms continuously passed through living susceptible intestines either increase or retain their virulency, which would cause the mortality among those attacked throughout an epidemic to remain the same. That the reverse, however, is the case, may be seen by referring to the history of the cholera outbreaks in the Philippines and in other countries (the rate at the beginning being from 90 to 100 per cent. and soon falling to 40 per cent. or below), so that the decline in the mortality would seem to be due rather to the acquired resistance of the individual than to the change in the cholera vibrio.

It appears probable that the cholera organism is conveyed either directly or indirectly from the sewers to easily contaminated articles of food or drink by the means of roaches, either by direct mechanical contact with their feet or bodies, or by the deposition of their intestinal excretions, thence to human beings; however, flies, water bugs, and other vermin, commonly found in sewers are also, no doubt, partly responsible. When it is remembered that cholera organisms can live in the intestines of such vermin for a number of weeks, it will be at once apparent that many cases of cholera, the origin of which has heretofore been obscure, will have at least a reasonable explanation. An outbreak of cholera such as occurred in Honolulu during the latter part of December, 1907, might also be explained by the landing of infected roaches.

As soon as proper health measures are put into effect to provide for the disinfection of the stools of infected persons, and the community gradually acquires a temporary immunity, the outbreak slowly subsides, and the disease does not again make its appearance in Manila until it is either introduced from the outside, or the cycle given above is repeated. It is conceivable that the immunity which has been referred to above is due to drinking city water, which contains an attenuated cholera vibrio, but this does not appear probable. The outbreaks in the provinces which are separated from Manila by open sea seem to be due to infected food, especially in view of the observation made by Dr. Cullen that the first persons attacked last year in northern Samar had all eaten a poor quality of dried fish brought from Manila.

The next paper, entitled "Studies in Cholera," was read by Dr. Harry T. Marshall, Biological Laboratory, Bureau of Science and Professor of Pathology and Bacteriology, Philippine Medical School. In this paper Dr. Marshall showed that there is a wide difference between individual strains of the cholera organism and that the virulency varied greatly. From a series of guinea pig inoculations which he made he stated that there are apparently deep set differences in the biological characteristics, and that there is a wide variation in the morphology and cultural characteristics in the various strains of cholera bacilli, and that so far as he has investigated the subject he has not found a single unalterable characteristic, variation being so frequent and complex that the question might be raised whether we are justified in regarding the cholera vibrio as an organism in the stage of mutation. By selection it is possible to develop cholera variants whose virulence is enormously increased and whose cultural characteristics are markedly different from those exhibited from stock cultures. A comparative study of the subject suggests that possibly the cholera vibrio is capable of living in the water supply of the Philippine Islands. Observations made upon patients in more than fifteen different instances after they had clinically recovered from cholera showed organisms in their stools, which indicated that they might act as cholera carriers for an indefinite period.

The next paper, entitled, "Tuberculo-Toxoidin and Immunization Serum," by Dr. T. Ishigami, Director of the Ishigami Institute for Infectious Diseases, Osaka, Japan, was read by title.

OUR LONDON LETTER.

(From Our Special Correspondent.)

A PROPOSED SPECIFIC TREATMENT FOR LEPROSY—SAWYER ON HEART DISEASE—EFFICIENCY OF DISINFECTANTS.

LONDON, April 10, 1908.

A CURE for leprosy! Alas that the expression should seem so absurd, but medical science is never hopeless, and those who heard Professor Deycke's lecture at the Tropical School admit that he has made a step in advance, though as to how many more steps remain to be taken they appear to differ. Dr. Deycke was the Director of the Military Medical School at Constantinople and has come here to seek permission to try in some of our dependencies a new treatment which he has devised. His researches, he said, extended over nine years of official work in Turkey in collaboration with his assistant, Dr. Reschad Bey. They began by trying to grow the lepra bacillus, but did not obtain it in the form seen in the disease. Yet they isolated from nodular leprosy an organism which they named *Streptothrix leproides*. The professor admitted that he

could not state with certainty the relations, if any, of this to the real *Bacillus lepræ*, but sure that it was not an accidental imparity, he ventured to inject a small quantity into a very severe case. Only a slight induration followed, but the patient declared it did him good and so earnestly begged for repetition that he was gratified with weekly injections. The leprous symptoms retrogressed so remarkably that in two months the patient declared he was cured and left the hospital. It would be interesting to hear his later history.

Large quantities of the new streptothrix were then cultivated and investigated, with the result of finding a well defined chemical, which they named nastin. This is the glycerin-ester of a high-molecular fatty acid. To injections of this lepers reacted in various degrees, some so excessively as to threaten life, others not at all. Further elaborate researches to account for and regulate these differences led to the employment of benzoylchloride in combination with nastin. This proved more certain and constant in its influence and eliminated the dangers of pure nastin injections, so that Dr. Deycke highly recommends benzoyl-nastin as an agent which acts directly on the lepra bacillus and it well adapted for general use as a remedy for leprosy. Not that it is an infallible specific, and to forestall mistaken conceptions Dr. Deycke pointed out the limitations and capabilities of his method. There are nodules, even in comparatively fresh cases, he told us, which respond but slightly or not at all to injections, while on the other hand there are large leprous formations which are done away with as promptly as are syphilitic eruptions by mercury. He thinks that we may count on arresting the leprous process and often more than that, except, of course, in the most advanced and hopeless cases. Photographs and lantern slides were shown in support of his opinion, and very remarkable they were. I will not trouble you with his theory as to the *modus operandi* of the benzoyl-nastin or nastin-benzoyl, but simply add that while some are saying it may be a step in advance, I think that, if corroborated, the step will be a very long stride indeed.

The Lumleian lectures at the Royal College of Physicians have been delivered this year by Sir James Sawyer, who took for his subject "Points of Practice in Maladies of the Heart." In his first lecture he took a brief retrospect of the progress made in the nineteenth century, particularly the later three-quarters, in which period no other branch of medicine had, he thought, made more brilliant advance. The methods of investigation had been multiplied, their applications refined and their results differentiated more and more. The older methods had not been superseded, but elaborated, and our views developed. We recognize the frequency of these affections and physiology has shown us that at the center of the circulatory system there lies and works the cardiac musculature, and near the periphery the musculature of the minuter arteries, and on these two instruments of power many influences are constantly acting and reacting. The heart in its complex functions, in health and its manifold derangements in disease, is the active center, the "prince of the commonwealth," as Harvey called it, in a vascular system of arteries, veins, capillaries, lymphatics, ductless glands, the blood, and tributary fluids. The circulating lymph is slowly moving, from the blood and back into it, bringing what it has gathered from every part. We now know the importance of the lymphatic inoculation; how great is the amount of lymph in the healthy body? Twenty-five per cent. of the weight, *i.e.* three or four times the amount of the blood. As to the ductless glands, Cyon has lately developed his hypothesis that the thyroid, adrenals, and pituitary glands regulate the cardiac nerves, and even that the action of the pneumogastrics is maintained by the secretion of the thyroid. But a wider view had to be taken, for this complex system was but one of the many other "systems" of the body, and not one of them but is always in touch with it. Therefore, a heart case, whether functional or organic, is never a heart case only. Our theory of yesterday was a neuromyogenic, with an allowance for contractile spontaneity in the heart's musculature, resting on metabolism. Recent researches give fuller knowledge of the play of this musculature, and its action and interaction with the cardiac innervation. The theory may be called myoneurogenic and is of the greatest importance clinically. Now we know that the initiation of the heart's beating is inherent in its musculature, and this is a remarkable safeguard for the continuance of the beat and even for its recovery after momentary suspension from shock, motion or otherwise.

In his second lecture Sir J. Sawyer passed on to consider the methods of physical examination. Inspection, he said, was a mode of minimizing errors of malobservation and of excluding those of nonobservation. In most healthy persons the impulse can be seen in its natural position. This spot, often called the "apex beat," as Waller has reminded us, is misnamed, for the apex really lies much deeper. It would be more exact to speak of impulse beat as the spot where the convex ventricular mass comes in contact with the chest wall, for the systolic bulging of the ventricle is the main part of the impulse. Inspection regards the physiognomy of disease.

As to this the lecturer spoke of cardiac distress orthopnea and Cheyne-Stokes respiration. From a study of the last he had devised a clinical test—placing a watch upon the middle of the sternum of a patient lying on his back and telling him to hold his breath. A healthy adult can do so for a quarter or perhaps a third of a minute. A patient with chronic heart disease may hold it for half a minute or longer, even if his breathing be hurried by cardiac apnea. It would appear that weak systoles of the right ventricle lengthen the time during which the breath can be held, perhaps because the blood-tension in the pulmonary circuit is subnormal and so is longer than normally in rising enough to compel inspiration. The test the lecturer found of use in degenerative, fatty, and sometimes in chronic valvular disease with failing compensation. He thought when the breath could be held longer than in health, there would be little or no blocking of the pulmonary circuit.

Under palpation the lecturer referred to the weakened impulse in adynamic diseases and concealment by emphysema, and the increase in force and area in hypertrophy. Dilatation, fatty change, effusion may lessen the impulse or render it imperceptible. Valvular thrill, at first thought to mark mitral disease, may be met with in any of the four valvular diseases of the left side of the heart and seems to need for its origin a rippling current in forcible motion. Anæmia may assist, as it can set up a minor thrill itself, but that is easily differentiated. True thrill always means valvular disease. But there is a gentle, systolic "tickling" thrill in nervous palpitation, coming and going with its own bellows sound (*bruit de consultation*), which might be called *frémissement de consultation*. It comes and goes in half a dozen beats—no *bruit*, no *frémissement*.

Turning to consultation, the lecturer held that no other department showed a progress more decisive, complete, and illuminatory. Every sound that the ear can distinguish had been recognized, traced to its origin, and its diagnostic and therapeutic indications made out. He then passed on to point out the advantages of the solid over the hollow stethoscope, especially in the investigation of heart cases. Though the hollow tube is so commonly used acoustics teaches that vibrations are conducted farthest and with least loss of intensity through solids firstly, next through liquids, and lastly through gases.

Sir J. Sawyer has modified somewhat the solid instrument, lengthening it to fifteen inches and leaving it unpolished, as that is warmer to the touch. Comparing the solid and hollow, he said one could hear well with a tube, as its walls were solid enough for conduction, but the pitch is higher and so more striking to the ear with the solid, which further brings out better the soft, short, low-pitched puffs of the systolic bellows sounds that characterize one kind of neurotic disturbance.

The efficiency of disinfectants concerns the public even more than the profession, and yet there is very little effort to prevent fraud. Professor Hewlett declared at a meeting in the Tropical School last week that the public is being continually defrauded by having foisted on it various so-called disinfectants which have no germicidal action at all. It is obvious that when such an article is used the danger of the spread of infection is increased by the reliance placed on an ineffective agent. The Rideal-Walker test has now been adopted by the War Office, the Admiralty, and other authorities. Dr. Rideal gave a demonstration of his method at the Tropical School (Sir P. Manson presiding). Vigorous cultures of typhoid were employed, the test consisting in a comparison of one portion exposed to the action of a standard strength of carbolic acid, and another to that of the disinfectant to be tested. The method has been recommended for adoption by the Committee of the Royal Sanitary Institute, appointed to inquire into the method of determining the efficiency of disinfectants.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 16, 1908.

Chronic Obstruction of the Duodenum by the Root of the Mesentery.—In contrast to the acute symptoms caused by the factor mentioned in the title of his paper, E. A. Codman calls attention to the fact that the same causes may produce trouble in milder and more subtle ways. His contentions are these: (1) That in the human being the transverse portion of the duodenum is more or less compressed by the root of the mesentery. (2) That slight anatomical deviations from the normal or certain

pathological conditions may increase this pressure to a varying extent up to the point of complete occlusion of the gut. (3) That when this pressure reaches a degree great enough to give more resistance to the muscular efforts of the duodenum than the closed pylorus, the condition becomes of pathological significance. (4) That thus anatomically the duodenal secretions are brought in contact with mucous membranes unfitted physiologically to withstand their corrosive action. (5) That the obstruction favors stasis in the duodenum and thus bacterial invasion of the tissues. (6) That if the above propositions can be proved they will materially alter the present conceptions of the etiology and treatment of a variety of pathological conditions, *e.g.* hyperchlorhydria, nervous dyspepsia, duodenal and gastric ulcer, pancreatitis, cholelithiasis, persistent vomiting after laparotomy and in pregnancy, and excessive fluid drainage from wounds in the common duct and duodenum. The paper is an elaboration of the propositions advanced in the foregoing paragraphs. The author reports one successful operative case in which a perforation existed in the common bile duct which was partially obstructed and says that the case is illustrative of a group of common duct cases which usually die from duodenal leakage through a patent dilated papilla.

New York Medical Journal, April 18, 1908.

Multiple Tape Worm Infection.—R. L. Wilson reports the case of a man of 39 years who was passing segments of tapeworm. He was given male fern with the usual dietetic restrictions, laxatives, etc., and passed a mass containing 13 heads and 319 measured feet of worms. The identification of the worms was based on the appearance of the heads, the size and shape of segments, the rosette uterus, and the appearance of the eggs. This finding was corroborated by laboratory examination.

A Retrospect of Phthisiotherapy.—H. F. Stoll has brought together in an interesting paper the various theories regarding the pathology and therapy of tuberculosis which have been recorded in the annals of medical science. His researches traverse the general progress made from the time of the founders of medicine down to the modern ideas of fresh air and sanatoria. As such studies almost invariably show, some of our modern "discoveries" are but the renaissance of conceptions which were exploited centuries ago and then abandoned.

Principles of the Climatic Treatment of Children.—F. L. Wachenheim says that we have two methods of applying physical therapeutics of all kinds, including climate. One consists in training or developing the diseased body or organ by exercise, the other in aiding the restorative powers of nature through reduced functional activity, or what we may briefly call, in the German fashion, a rest cure. The former is indicated when the body or any of its organs suffers from imperfect development or functionates poorly from disuse. A course of training, likely to be ineffectual or even dangerous in advanced life, is almost certain to yield excellent results in childhood, if applied with judgment to patients affected with such diseases as, for example, rickets or scrofulosis; it is very generally agreed that removal to a stimulating climate is of the greatest benefit to these cases. When, however, the body or any of its parts is already overstrained and for that reason unable to cope with the work that normally falls to it, a rest cure is called for. Here, likewise, the indication is more urgent in childhood than later, for in the young subject overwork entails far more danger of permanent impairment than in the adult, and, on the other hand, there is a much better chance of complete, or at least satisfactory, restitution if appropriate measures of resting be applied, a sedative climate being one of the very best of these. Climatic rest cures are especially indicated in such affections as nephritis and uncompensated cardiac lesions. The author notes that the restful temperature varies greatly according to age. Thus, say 78° F. is decidedly bracing for growing infants, and indifferent for children just able to run about, but too warm for older and active children. Young children stand severe cold badly and a cold mountain climate is hardly advisable before the tenth or twelfth year. An important matter is the relative humidity at high temperatures, for such conditions as call for free transpiration when we desire to relieve the kidneys by diaphoresis. Here a warm and moist climate is indicated as being the best mild diaphoretic known. The anemias of young subjects do best at the modern elevation of our Eastern mountains and the same is true of the victims of general malnutrition, rickets, scrofulosis, and chronic tuberculosis.

The Most Useful Specialty in Medicine.—J. M. Taylor says that every person, young and old, is capable of a notable increase in vital status by a revision of modes of life. This is particularly demonstrable as middle age approaches and tissue elasticity subsides. On this basis, there would seem to be, he says, ample work in any community for specialization in systematic amplification of efficiency. One difficulty is distrust and jealousy which discourage frank consultation and cooperation and another is the supineness of the profession in omitting to compel recognition of the high pecuniary value of expert advice in the conduct of life. In the process of enhancing vital powers there are diverse, well known, excellent resources, often wisely employed. These embrace such familiar measures as regulation of life on a hygienic basis, including all those factors which contribute to physical economies, to normal activities, as by open air life, dietetic care, correction of functional or constitutional errors by well chosen drugs, and the like. These are efficacious in proportion to (1) the judgment and care exercised by the adviser in searching out causes, and (2) to the degree of cooperation supplied by the individual. Success depends upon a thorough estimation of the specific needs of each person. The main principle is the importance of securing greater elasticity of the tissues and promptitude in the reactive times between controlling centers and outlying motor parts. Full organic competence is not sustainable unless the supporting structures are maintained in normal degrees of mobility. By securing greater elasticity in the less used structures we can accomplish improvements in many unexpected directions, among the chief of which is the securing of harmonious interreactions through systematic motor stimulations. The author lays special stress on the necessity of increasing the activities of the paravertebral tissues. By encouraging activities in these paravertebral muscles, and securing elasticity in the ligaments in the back, there follows a corresponding and correlated enhancement of all organic activities. This can be readily accomplished by systematic posturings, torsions, bendings, etc., alone or along with extensions of the limbs and systematic forced respiratory acts, whereby the junctures of the ribs and backbone are made more mobile. The key to erectness, hence of skeletal efficiency and visceral interrelationship with the maintenance of organic competency lies in the keeping of the thorax in a normal posture. To secure this thoracic normality requires intelligent motor education. By the simple device of training a patient to clasp the hands behind, pulling apart strongly and pushing the arms forcefully down, at the same time thrusting up the chin verically, these contractured tissues are forcefully stretched, perhaps for the first time in years. This act repeated, and with steady increments of force, widens the front of the thorax, educates the downpull of the erector spinæ muscles, and overcomes the common and damaging habit of stooping. Stooping always induces undue compression of the larger viscera.

Journal of the American Medical Association, April 18, 1908.

Malignancy in Warts and Moles.—The danger of the malignant degeneration of warts and moles is hardly sufficiently appreciated by either the medical profession or the public in the opinion of E. A. Babler, who reports a series of cases observed in the St. Louis Skin and Cancer Hospital. It is true that a wart or mole may never become malignant, but a study of the literature, together with his own personal observation, convinces him of the reality of the danger. In some cases a more or less constant irritation seems to be the exciting factor, and in others a slight injury, such as an insect bite or a cut received in shaving seems to start the growth into malignancy. Most of his cases had their origin in warts. One difficulty experienced is the reluctance of patients to permit operation early enough to check the morbid process. He fully agrees with Keen who contends that the moment warts and moles begin to increase in size they are almost always already malignant growths and should be treated as such. He protests against the practice of cauterizing warts on the face; they should be excised.

Hypertrophy of the Prostate.—A. J. Crowell holds that hypertrophy of the prostate is always or nearly always due to congestion or inflammation. He bases this belief on the frequency with which it occurs in comparatively young persons as well as on the pathology. He has seen it in a boy 8 years old and in a number of men between 30 and 40. Most of these patients gave a definite history of acute infection in early manhood, and while this is not absolutely essential, it is the most common cause. The reason why it is most frequent in the aged is twofold; First, each year lengthens the time for infection and continued inflammation with its increasing obstruction; and second, it occurs at that period of life when lack of tone and senile degeneration make themselves manifest. According to this view, pathological hypertrophy is a preventable condition in many cases, and the treatment is prophylactic, palliative, and operative. The prophylactic treatment consists in the use of heat, massage, dilatation, and various

medicinal remedies. The palliative treatment consists in catheterization, intravesical irrigation, vesical sedatives and urinary antiseptics. The operative treatment is palliative and radical. Palliative measures, such as cystotomy, are only resorted to in extreme cases when prostatectomy is not advisable. Prostatotomy or the Bottini operation are indicated in a limited number of cases—those in which the median lobe is small—and even these patients will do better with perineal section. For radical treatment he favors the perineal operation as being less mutilating and less serious, and especially as better preserving the sexual powers.

Occupation for the Insane.—E. Cohn remarks on the value of occupation in the treatment of the insane, as well as on the difficulties in providing it, which are experienced even in well-managed institutions. He describes the method which has best served him in meeting the problem, the main feature of which is a regular systematized program for each hour of the patient's day, and including arrangements for physical exercises, graded calisthenics, ward work, mental occupation in the form of games, reading, etc., all directed according to the patient's capacity and changed daily as much as possible to secure variety. Entertainments, music and all kinds of rational outdoor sports should be provided for, and every kind of special talent be utilized among patients and employees. Of course, hearty cooperation is required on the part of the attendants, but this is easily secured by proper enforcement of discipline. Attendants and nurses generally fall in readily with the arrangements as helping to render their duties less monotonous. A reasonable amount of "time off duty" should be allowed to better prepare them for their task. Attendants are liable to think amusements, etc., are to be used as rewards for good behavior, but this is a mistake; it is the irritable, restless, and depressed patients who are most in need of them, and the physician should be the judge.

Pernicious Anemia.—W. J. Stone reports a case of pernicious anemia in which the blood count had fallen to under 300,000, with marked poikilocytosis. The patient, a man, apparently fully recovered, having been in perfect health and able to do arduous manual labor for the past year. The treatment was mainly with sodium arsenite, grain 1/10 every four hours during his stay at the hospital, together with injections of normal salt solution for a couple of weeks. The case, Stone thinks, emphasizes the facts that such cases are not altogether hopeless, that the prognosis depends on the degree of red-cell regeneration in the bone marrow, the age of the individual and the potency of the hemolytic poison, and the further fact of the rapid specific influence of arsenic on blood regeneration in certain of these cases. Whether this is through direct stimulation of the bone marrow activity or through neutralization of the hemolytic poison, or both, remains undecided.

General Anesthesia.—O. J. Cunningham has devised an apparatus for the administration of nitrous oxide and oxygen with the ether sequence, which, he claims, possesses the following advantages: If necessary, oxygen can be given pure or mixed at any time during the anesthesia or afterward to bring about a quick resuscitation. A few breaths of oxygen will completely relieve the occasional laryngeal spasm of incomplete anesthesia without decreasing the amount of ether being used. A special feature is that the gases and ether vapor are accurately measured under all conditions, allowing a perfectly even administration, and thus adding to the safety of the patient and the convenience of the operator. By mixing oxygen in the proper proportions with nitrous oxide, complete narcosis can be maintained indefinitely and is used sufficiently long (from three to five minutes, occasionally longer) to permit ether to be administered gradually and slowly until complete ether narcosis is established. The swallowing of the ether-laden hypersecreted mouth secretions is thus avoided, with its consequent nausea and vomiting. The danger of aspiration pneumonia is also thus lessened. The reduction of body heat by the ether, which is liable to occur under the ordinary methods, even in a warm atmosphere, is avoided by the combined employment of three methods: 1. The ether chamber is in a bath of 22 ounces of water, at about 90° F., a little below the boiling point of ether. 2. Ether, and the corresponding refrigeration, is saved by the quick induction of complete narcosis by nitrous oxide and oxygen. 3. Only the inhalation passes over the ether and not both inhalation and exhalation, as is the usual rule. This saves half the ether ordinarily used and also reduces refrigeration. Rebreathing, with its decreased oxygenation and increased carbonic acid is practically impossible with this apparatus. The apparatus complete (exclusive of the gas cylinders) weighs 20 pounds and can be carried in a case smaller than the usual suit case. The expense of anesthesia by this method is not excessive, and there are practically, he claims, no uncomfortable after-effects.

The Lancet, April 11, 1908.

The Cell as a Factor in Phagocytosis.—H. A. Bayly has made 88 determinations of the tuberculoopsonic index on 44 women in labor with a view of endeavoring to ascertain whether fatigue lowered the power of resistance to infection by acting on the cell or the serum. With each patient's serum he made two determinations of the tuberculoopsonic index, in the one case using the patient's own cells and in the other using his own cells. He found, using his own cells, that in 39 cases the index was between 0.8 and 1.2. Of the remaining five cases three were above 1.2 and only two below 0.8, thus confirming Western's conclusion that fatigue does not lower the opsonic content of the serum. When the patient's own cells were used, however, the result was very different. In only 19 cases were the indices between 0.8 and 1.2; 25 were below 0.8 and none was above 1.2. Still more marked was the relation of the index found when the patient's cells were used to that found when his cells were used, for the index was lower with the patient's own cells in 38 cases and higher in only four, while in two the index was the same with both the patient's cells and his cells.

Renal Hemorrhage in Chronic Interstitial Nephritis.—J. T. Macnab gives a general description of the condition referred to and presents the histories of three cases. As to treatment he says that rest in bed, purgatives, and a diet consisting chiefly of milk, eggs, and bread-and-butter will, as a rule, be sufficient to stop the bleeding. Hemostatic drugs, such as calcium lactate or calcium chloride, may be tried, but are hardly necessary. Iron in some form will be useful during convalescence. Thirty-eight of the cases which the author collected were so treated, and with the exception of three deaths all recovered. The three deaths were in advanced cases, all of the patients having retinal changes and other signs of marked cardiovascular degeneration. Recurrence is extremely probable, for the cause, the chronic nephritis, still remains. One patient was explored for a renal calculus which did not exist, and died ten days later. Surgical treatment has been tried in a number of cases; where no changes in the fundi can be detected and the patient's general condition is good enough to warrant the administration of a general anesthetic, operation may be advisable to check bleeding which does not react sufficiently to medical treatment. Two methods of operation have been practised with some success. In the one, introduced by Edebohls, the capsule of the kidney is removed as entirely as possible. He even claims that this procedure has a curative effect on the nephritis itself. Four cases were treated in this way; in all the hematuria ceased for a time, but two relapsed within a few months. The other method is described by Fenwick. He believes that the blood escapes from the lower pole of the kidney; he therefore makes an incision into this part of the kidney substance without opening the renal pelvis. This causes a scar to form which obliterates the vessels reponsible for the bleeding, and so stops it.

Rational Treatment of Functional Dyspepsia.—R. Hutchison classifies the disorders of gastric function giving rise to symptoms of functional dyspepsia, as follows: A. Secretory, (1) excess, or hyperchlorhydria and hypersecretion, (2) defect, or hypochlorhydria and achylia. B. Motor (1) excess, or pyloric spasm, (2) defect, or atony and motor insufficiency. C. Sensory, (1) excess, or hyperesthesia, (2) defect, or anorexia and achoria. Details of treatment are given under each one of these subdivisions. The author says that any one of the foregoing disorders may occur alone, but two or more are frequently found coexisting and giving rise to a group of symptoms characteristic of certain clinical types of dyspepsia. For instance, it is common for an excess of secretion to occur along with some hyperesthesia of the stomach in some forms of so-called "acid dyspepsia," and to these there may be superadded some excess of motility in the form of pyloric spasm; or there may be a greater or less degree of motor insufficiency with or without some disorder of secretion in what is commonly spoken of as "atonic dyspepsia." This, at least, is certain—that, did our knowledge only permit of it, every case of dyspepsia could be analyzed into a disorder of one or more of the above functions of the stomach, and that accurate treatment depends upon the degree to which such an analysis can be carried out. Concerning general treatment of this class of cases as a whole, the author observes that inasmuch as disorder of the functions of the stomach is in most cases and in the last resort the expression of a disturbance of the nervous mechanism of the organ—that is, that dyspepsia is really only one way in which functional disease of the nervous system manifests itself—it will be obvious that treatment

directed to the nervous system is applicable in all cases. It is in this way that such therapeutic agents as rest, liberation from worry and mental work, change of air and scene, and many of the "hydrotherapeutic" measures exert their beneficial influence, and the use of such agents is in the strictest sense rational.

British Medical Journal, April 11, 1908.

Parotitis as a Sequel of Pneumonia.—G. B. Robinson's patient was a man of 42 years whose pneumonia terminated by crisis on the seventh day. Next day his temperature began to rise, and on the third day after the right parotid began to swell. Incision revealed no pus, but it appeared later. As toxic symptoms came on and drainage was insufficient, deeper incisions were made and various pus foci uncovered. The wounds healed in about a month after the onset of the swelling. The pus showed *Staphylococcus albus* but no pneumococci. The case was therefore probably due to oral sepsis. The author makes a plea for greater cleanliness and for care over the oral cavity in every case of illness, no matter what its nature.

Therapeutic Use of Normal Serums.—E. C. Hort reports series of cases treated with (1) local applications of serum, (2) internal doses of serum, (3) both methods combined with vaccines and (4) vaccines (internally) alone. The cases cover a wide range of lesions, such as fissures, varicose ulcers, bed sores, gastric and duodenal ulcers, pustular eczema, tuberculous hemoptysis and sacroiliac disease. His therapeutic results have been surprisingly good. Brief notes of some of the cases are given. The author says that in the cases of arrest by the serum of progressively destructive lesions caused by the tubercle bacillus, it seems highly probable that such arrest is due to an increase in the inhibitory power of the blood. This raising of the clinical index of the blood's inhibitory power is likely to prove to be the expression of the reaction of the organism to normal serum treatment in all cases of cell destruction, whether due to bacillary invasion or not. It is more than probable that the opsonic index, which after all is only a measure of ingestion prior to lysis of bacteria, will be found to be only a supplemental factor to the true antilytic index of response, which is a gauge not only of antilysis but of restrained lysis. It is conceivable that ingestion and subsequent lysis of bacteria may give rise to an undesirable escape of poisonous enzymes, unless restrained from running riot by antilytic action. Opsonic estimation is and can be only a partial indication of the organism's response to bacillary invasion or vaccine injection. An index of antilytic response may prove to be a far truer guide. The action of normal serum would appear to be a sum of the two opposing actions of an antilytic and auxilytic body. The protein constituent of the serum with which the antiantolytic body is in combination is still a matter of dispute.

Berliner klinische Wochenschrift, April 6, 1908.

The Antiferment Action of Human Blood.—Marcus describes tests and amplifications of the Müller method of determining the antiferment content of the blood. This consists in using leucocytes as a test object by mixing the serum and inflammatory exudate in different proportions and placing drops of the mixture on the surface of Loeffler's serum plates, which are kept in the incubator at 53° for twenty-four hours. If the antiferments of the blood have neutralized the tryptic ferment of the pus cells no digestion of the serum medium takes place, otherwise at the site of each drop a little depression is formed. Marcus has found that the method is a good one but suggests the modification that instead of pus, which is inconstant in composition and often difficult to obtain, a definite solution of trypsin be used as test object. For this purpose a 1 per cent. solution of the ferment is suitable, and he has found that the antitryptic power of the blood serum may be considered normal if when mixed with three times its volume of 1 per cent. trypsin solution it prevents the formation of hollows on the surface of the serum plates. Therefore, it is reduced if it can neutralize only less than this amount, and is increased if it can neutralize more. Observations on patients suffering from various affections, mostly chronic in nature, showed that the antiferment content of the blood is subject to variations, lymphatic leukemia especially being characterized by a very high amount of antiferment.

The Effect of the Reaction in Wasserman's Syphilis Test.—Sachs and Altmann have found in working with Wasserman's complement fixation test for syphilis that the reaction of the serum used is of importance. In ten cases tested, it was found that whenever the alkalinity of the complete mixture reached 1-800 to 1-3,200 N. NaOH the positive reaction was either prevented from appearing or else, in the case of very strong sera, was greatly reduced. On the other hand it was possible to cause a positive reaction to appear with nonreacting sera by the addition of a small amount of acid, so that the mixture had an acidity of 1-1,000 to 1-2,000 N. HCl. Two explanations of these facts are offered. Either syphilitic sera are distinguished from others only through a diminished alkalinity, or a diminished alkalinity is necessary for the changes observed to take place. The authors incline to the latter view as it was never possible to obtain a positive reaction in normal sera by the addition of acid.

Münchener medizinische Wochenschrift, April 7, 1908.

Testing Pus with Millon's Reagent.—Dreyer has tested the pus from seventy-three different cases with Millon's reagent in the manner suggested by Muller as a means of differentiating between tuberculous and nontuberculous processes. The procedure is carried out by allowing a drop of the fluid in question to fall into a small dish containing the Millon's reagent, which consists of a solution of mercury in nitric acid. Tested in this way ordinary pus forms a disc in the fluid which is readily broken up by means of a platinum needle, whereas tuberculous pus forms a pellicle which is dense and firm so that it may readily be lifted out with the wire, and if it is plunged below the surface of the fluid it makes a globular mass. After the lapse of a few minutes the Millon's reagent to which the ordinary pus had been added turns pinkish, but if the drop was of tuberculous origin this change is not observed. Dreyer found that the test was reliable, though in tuberculous cases the presence of a secondary suppurative process caused the exudate to give the reaction characteristic of nontuberculous material. The pus should not be tenacious, and must be obtained without the admixture of much blood. If the drop forms a dense membrane the process in question is undoubtedly a tuberculous one, but if the other type of reaction is obtained there must be present an infection with the ordinary pus producing organisms, though there is the possibility that the underlying condition is tuberculous. As the treatment, however, is the same whenever there is an acute infection, the method is valuable for practical purposes.

A Simple Method of Testing the Pancreatic Function.—Schlecht has found that the following method furnishes a satisfactory means of determining the functional efficiency of the pancreas. The patient's lower bowel is cleared out by means of an enema and he is then given a test meal. One or two hours later an active purgative is given, such as calomel, and then droplets of the resulting stools are scattered over the surface of serum plates and kept in the incubator for twenty-four hours at a temperature of 55° to 60° C. If trypsin is present in the stools it shows itself by the formation of minute hollows on the surface of the plate, while if the stool contains none, these do not appear. Tests on animals and on patients indicate that the procedure is reliable in its results, while it is also simple and easy to carry out. Further investigations will probably enable it to be used also as a quantitative method.

Surgical Treatment of Rhinophyma.—Gersuny recently operated successfully in a case of this nature, and the operation is thus described by the Vienna correspondent of the *Lancet*. The procedure was done under local anesthesia produced by a solution of cocaine of 1 per cent. strength, only a few grains of the alkaloid being used. The tumors were incised near their border, so that the underlying cartilage was exposed. Then the skin was undermined all around, and the tumor removed, thus leaving a free narrow edge of true skin everywhere. This free edge was fixed to the wound by a few sutures. The saving of this free edge is important, as it serves as a margin for the tip and the edge of the nose. Then the remaining wound was covered by flaps of epidermis taken from the extirpated tumors. The dressing consists of gutta-percha tissue fixed to the skin by means of chloroform. The dressing can be removed after four or five days. The chief advantages of this method are: (1) the natural appearance of the nose is preserved after the operation because there is no difference in color between the new skin and the surrounding parts of the face; and (2) the removal of the large masses tends to improve the vascular condition in the face, so that the often concomitant acne rosacea disappears or is much diminished. Seven patients have hitherto been operated upon by this method with very good results.

Book Reviews.

Pathology, General and Special. For Students of Medicine. By R. Tanner Hewlett, M.D., F.R.C.P., D.P.H., Professor of General Pathology and Bacteriology in King's College, London; Lecturer on Bacteriology, London School of Tropical Medicine, Physician to the Seaman's Hospital, Greenwich; Examiner in Pathology, University of Aberdeen; Examiner in Tropical Medicine, University of London. Second Edition. Philadelphia: P. Blakiston's Son & Co., 1907.

The present volume is a successful attempt to give, with quite enough detail for the medical student and practitioner, all the essentials of general and special pathology. There is no pretense made to include every hypothesis and theory that has ever been offered, nor does the author befog the reader with an unusual terminology; at the same time nothing is included that the student will have to unlearn. Most medical students require only such knowledge of pathology as will aid them in the practice of their profession, and the book under notice fills this bill most satisfactorily. The former edition was exhausted in a year, and the present edition, besides having undergone a careful and thorough revision, contains some new matter. The chief additions have been made in the sections dealing with heredity, the degenerations and infiltrations, neoplasms, inflammation, the infections, the heart, and arteriosclerosis. This book is a valuable addition to the present textbooks on pathology, and for the general practitioner it is one of the most useful; not the least among its many good points is the fact that its author is a physician as well as a pathologist.

Die Augenheilkunde in der Römerzeit. Von Dr. Rodolfo del Castillo y Quartiellers, in Madrid. Autorisierte Ubersetzung aus dem Spanischen von Dr. Max Neuberger, Professor an der K. K. Universität in Wien. Mit 26 Textfiguren. Leipzig und Wien: Franz Deuticke, 1907.

This fully illustrated brochure of 137 pages gives a very interesting history of the practice of ophthalmology by the Romans from the time of the rise of medicine under Augustus to its decline after Nero. In addition to available ancient literature, the author has made use of the legends that have been found on stamps, signets, tablets, and containers of various forms and sizes; of sculptures in relief, bronzes, and of various instruments and implements used in ophthalmic practice that have been unearthed from time to time during excavations that have been carried on in various places, for the data from which to present the subject. These objects of archeological interest belong to various museums, where they have been studied in this connection. About two hundred examples of stamps and signets are so held. Formulæ for a large number of collyria; methods of compounding; the materia medica then in use, and the therapeutics of ophthalmology are described quite at length. A chapter is devoted to the surgery of the eye, in which the various operations on the lids, lacrymal apparatus, and globe, as then performed, are described. The work is one of value and of great interest to those who desire to know something of the antiquities of ophthalmology.

Gallstones and Diseases of the Bile-ducts. By J. Bland-Sutton, F.R.C.S., Surgeon and Lecturer on Surgery to the Middlesex Hospital, etc. With 47 Illustrations. New York: William Wood and Company, 1907.

The contents of this book consist of the series delivered by the writer at the Middlesex Hospital, and have been published in this form with the idea of being useful to students. It constitutes a concise but valuable exposition of a subject which, notwithstanding its very voluminous literature of recent years, is still not sufficiently understood by the profession at large. A great number of cases of cholelithiasis go on unrecognized because of the lack of a general knowledge of their diagnosis in the earlier stages. Operative intereference here is now accepted as of as great importance as in appendicitis, and yet when we view the mortality statistics presented by the author, it seems to be a procedure, like most others of a major surgical character, not entirely free from grave risk. The book is written in Bland-Sutton's usual good style, and constitutes a very satisfactory manual for students. The only criticism to be made of the book is in the illustrations, which hardly measure up to those of recent years on similar subjects.

Tumors of the Cerebrum; Their Focal Diagnosis and Surgical Treatment. By Charles K. Mills, M.D., Chas. H. Frazier, M.D., Wm. G. Spiller, M.D., Geo. E. DeSchweinitz, M.D., and Theo. H. Weisenburg, M.D.

This book is made up of a series of seven papers, reprinted from various journal sources, of which the first deals with the focal diagnosis of operable tumors of the cerebrum, and is written by Dr. Mills. It presents an excellent résumé of the important differential points between this condition and other lesions of the forebrain. The same author also has a paper on the significance of Jacksonian epilepsy in focal diagnosis, and, in conjunction with Dr. Chas. H. Frazier, another on the motor area of the human cerebrum, its position, and subdivision, with some discussion of the surgery of this area. Cerebral decompression is treated by Drs. Spiller and Frazier, the ocular symptoms of tumor of the cerebrum, by DeSchweinitz, and conjugate deviation of the eyes and head and disorders of the associated ocular movements, by Dr. Weisenburg. These men have all had important associations with this line of surgical endeavor, and the book here noted affords in a convenient form the results of their united labors. A number of very excellent photographic illustrations add considerably to the interest of the book.

Zur Lehre von der Zwillingsschwangerschaft mit heterotopem Sitz der Früchte. By Fr. v. Neugebauer, Warschau. Leipzig: Verlag von Dr. Werner Klinkhart, 1907.

The question of a double pregnancy occurring simultaneously in different portions of the genital tract is a very serious one, because the prognosis is most uncertain, and the diagnosis, particularly in the early months, practically impossible. It would appear from the statistics collected by this writer that the condition is not an infrequent one, for he was able to obtain reports from the literature of 171 cases, which he presents as a very complete bibliography of the subject. This constitutes a most satisfactory exposition of the subject, and as such will serve as a valuable work of reference and information for those desiring greater knowledge of this interesting complication of pregnancy.

Die Behandlung der tuberkulosen Wirbelsäulenentzündung. Von Dr. F. Calot, Ubersetzt von Dr. P. Ewald, in Heidelberg. Mit 120 Abbildungen. Mit einem Vorwort von Prof. Dr. Oscar Vulpius. Stüttgart: Verlag von Ferdinand Enke, 1907.

Calot is the French orthopedist who, some ten years ago, announced a method of treating spondylitis which upset to a large extent the methods hitherto employed. He came boldly forward with the claim that the kyphos, which had been regarded as a necessary evil associated with the healing process in tuberculous disease of the spinal column, must not only be prevented, but, if already present, should be attacked as part of the cure. This revolution in the accepted methods of treatment did not last long, and the pendulum then swung so far in the other direction that only the most severe and hopeless cases of tuberculous spinal deformity were subjected to the radical measures which Calot advocated. The latter, undaunted, however, has brought out another work in which the technique of the treatment is somewhat modified and simplified in addition to such an extent that the methods can be applied by the ordinary practitioner without the use of elaborate special apparatus. The illustrations are excellent, and show exceedingly well the writer's method of applying the plaster jacket, which differs considerably in most of its details from that ordinarily employed. The German translator deserves a word of credit for the excellent reproduction of this important French work, and an English translation would undoubtedly meet with a favorable reception.

A Manual for Boards of Health and Health Officers. By Lewis Balch, M.D., Ph.D., Secretary State Board of Health of New York, Health Officer of Albany, Emeritus Professor of Anatomy and Professor of Medical Jurisprudence, Albany Medical College. Also the Public Health Law, constituting Chapter 25 of the General Laws, with all Amendatory and Supplemental Statutes, including those of 1907. Albany, N. Y.: Banks & Co., 1907.

This volume contains a practical statement of the duties of health authorities, and how they may be performed as required by the public health law of the State of New York. It is not a manual of hygiene, nor is it a legal work or an exposition of decisions rendered by the courts on health matters. The book will prove useful to all health officers and others concerned with boards of health. The article on the Practice of Medicine on pages 195 to 208 is a reprint of the old law on the subject and is now out of date. The general get-up of the book is poor; it could be improved by a proper system of pagination; there are far too many intercalated pages, and these represent different varieties of type and are also of varying lengths. In the index, too, if the numbers referred to pages (properly arranged) instead of to sections, it would be much easier to find any desired topic.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 26, 1908.

DR. W. S. STONE IN THE CHAIR.

An Asexual Monster; a Unique Specimen.—Dr. EDEN V. DELPHEY presented this specimen. Although the confinement was at full term, the child was only as large as a six months' fetus. The cranial bones were completely ossified. There was but one eye. The right palpebral fissure measured 17 mm., and the left 14 mm. The nasal processes of the supramaxillary bone and the nasal bones were hypertrophied and separated in the median line. There were but four fingers on each hand, and four toes on each foot. There were no external genitals. There were two ovoid elevations, empty cyst sacs, just over the site of the external ring, each about the size of an almond. The anus was patulous and in the anterior margin was shown a dimple marking the location of the urethra. There was but one kidney and no internal sexual organs whatever.

Carcinoma of the Vaginal Portion of the Cervix.—Dr. HERMAN J. BOLDT presented this specimen because of the question of doubt as to the justifiability of having done an extirpation of the uterus which arose after the receipt of the report from the pathologist. Clinically there was no doubt as to the breaking down ulceration present on the vaginal portion of the cervix being malignant. The woman was well advanced in the forties and had been having atypical bleeding and putrescent vaginal discharge for several months. When he received the report that the ulceration was not malignant, he was surprised and sent the same specimen to another pathologist, who reported that the cervix was invaded with nests of epithelial cells of the squamous variety. In addition there was a decided necrosis of the endometrium and endocervix, beneath which dense infiltration with polynucleated leucocytes had occurred. This showed that a report from a pathologist was sometimes not reliable if the pathologist did not take the time to examine the specimen carefully.

Adenocarcinoma of the Body, Complicated with Suppurative Tuboovarian Inflammation.—Dr. HERMAN J. BOLDT presented this specimen. The patient had had atypical bleeding for several weeks after a curettage. An examination of the scrapings showed adenocarcinoma. The patient made an uneventful recovery and was out of bed the day following operation. The operation was done by the abdominal route.

Hysterectomy Because of Intractable Bleeding.—Dr. HERMAN J. BOLDT presented two uteri. Both patients had had profuse uterine bleeding at times, and were never free from some loss of blood. The various treatments employed had been ineffectual. In one, a woman of 44 years, the scrapings were sent to the laboratory. The report was that the picture was suspicious of malignancy. The blood-vessel coats of both uteri showed pathological thickening; otherwise the changes showed a chronic endometritis. The ovaries in both cases showed chronic inflammation. Dr. Boldt had appended the pathological report on one of these cases, and hoped to induce operators to have each and every specimen that might be obtained by operation carefully examined; only by such means could they hope to learn more about gynecological pathology. Furthermore, by invariably adhering to this rule, they might occasionally save a life, because it would be found occasionally that a condition which they believed to be benign, was malignant.

Placental Polypus.—Dr. BOLDT presented this specimen. For three months subsequent to confinement the woman from whom the specimen was removed had had more or less profuse bleeding from the uterus. The tumor was attached to the fundus uteri. There was a suspicion that it might have been a deciduoma, but the pathologist's report did not confirm the suspicion. Within two days after the removal of the placental polypus the bleeding entirely ceased.

Dr. Boldt presented another specimen of placental polypus. The patient was told that she had carcinoma. She had aborted four months previously and since had been bleeding more or less profusely.

Cystic Tumor of the Round Ligament.—Dr. BOLDT presented this specimen. The patient had noticed for some time an enlargement in the right inguinal region which was diagnosed by her physician to be a hernia. She was admitted to the hospital for an operation on the pelvic organs, and he was requested to attend to the swelling in the groin. Dr. Boldt made no definite diagnosis. On cutting down upon the small tumor it was found to be continuous with the round ligament. The cyst wall was composed of fibrous tissue, loosely held together; in the meshes of the connective tissue were masses of leucocytes. The lining of the cyst was of fibrous tissue, and there were but few blood-vessels.

Specimen of Tubal Abortion.—Dr. BOLDT presented this specimen. The patient had aborted two weeks before entering the hospital, and had been bleeding continuously ever since. When Dr. Boldt saw her she was blanched, entirely pulseless, but in possession of her mental faculties. A rather superficial examination showed that the vaginal portion of the cervix was not succulent, the uterus was not enlarged or softened in consistency. The woman complained of severe pain when the vaginal portion of the cervix was moved forward. This was a symptom that he had observed for a number of years, and had learned to attach some importance to it. He did not know of anyone who had called attention to it besides himself. The pelvis was filled with an indefinite fullness. The Fallopian tubes could not be palpated. At operation the abdomen was found to be filled with blood which gushed out like a fountain, so soon as an exit was made for it. It was evident that the left tube was the seat of the faulty implantation of the ovum, and it was removed. The ovary was removed for the purpose of studying it histologically. The questions that were asked were: Was it ever desirable to delay operation in extrauterine pregnancy if the pulse was very poor? Yes, in exceptional circumstances. Could the diagnosis between tubal abortion and tubal rupture always be made? No, not from the clinical symptoms. Did an hematocele always form if tubal abortion occurred? No. In the case he reported the symptoms were just as serious as they were in an extensive tubal rupture, and death would undoubtedly have taken place from acute anemia, had the patient not been promptly operated upon. Did death ever take place from intraperitoneal hemorrhage because the operation for the removal of the gestation products had been delayed? Yes. He had had three such instances. In one case a diagnosis of extrauterine pregnancy was made and the patient was sent to the hospital. He intended to operate on the following morning. The woman suddenly went into collapse and died. An extensive tubal rupture had taken place into a preformed hematocele, and broken through into the peritoneal cavity. A second case was one in which the diagnosis was thought to have been colic from indigestion, or appendicitis, but which was diagnosed by Dr. Boldt as tubal abortion. Immediate operation was advised, but before consent was obtained another hemorrhage occurred and the patient died. The particulars in a third instance he could not then recall.

Dr. WILLIAM S. STONE said that he could corroborate what Dr. Boldt had stated about women complaining of pain when the vaginal portion of the cervix was moved forward in these cases of tubal abortion.

Dr. C. C. SICHEL reported a case of ectopic gestation he had operated upon a year ago; in this case an extraordinary amount of bleeding occurred and the patient

died. There was a ruptured ectopic gestation of the interstitial variety, and he believed that, in those cases, an immediate operation was demanded.

Dr. C. F. Adams distinctly recalled a case at the Columbus Hospital, a patient being brought to the operating room with no pulse at all. When given ether she seemed to become worse but, with the use of saline infusion, the bleeding practically stopped. After giving four ounces only of the saline infusion, the pulse fluctuated again and after six or eight ounces were given she rallied to a marked extent. He removed the right adnexa which had ruptured. On the left side there was a hydrosalpinx, and this he removed as well. The time consumed in operating was about twenty minutes. At the completion of the operation the patient had a good color and was sent to the ward in good condition. He believed that had the saline infusion not been given she would not have rallied. She was practically dead before its administration.

Dr. Boldt believed that in those cases it was better to begin the infusion when the patient was placed on the table, and not to wait until the end of the operation.

Dr. Adams said this was done in the case he reported.

Carcinoma of the Uterus, Complicated by Pus Tubes and Adherent Appendix.—Dr. C. C. Sichel presented this specimen. The patient from whom this specimen was removed was forty years old, married, and gave a negative family history. Five years ago she had an attack of what was supposed to be appendicitis or salpingitis. She had been married six years, had two children, but no miscarriages. She began to lose weight June 1, 1907. About August 30 she had a fainting spell, and was admitted to the hospital one week later. She had a bad vaginal discharge, more profuse at the time of her menses. The abdomen was distended and there was pain on pressure in the lower right quadrant. The cervix was enlarged, bled readily, with a foul smell, and there were whitish elevated areas. The cervix felt hard, but the tissues did not break off easily. The uterus was bound down, being only slightly movable. A portion of the cervix was sent to the pathologist, who reported it to be an adenocarcinoma. At operation the tip of the appendix was found to be adherent to the right ovary. The appendix was removed and showed an old catarrhal condition. The tubes were enormously distended and bound down by adhesions. A panhysterectomy was performed and the abdomen drained. The patient was in a critical condition for some time, but after a long siege left the hospital and was lost sight of.

Case of Right Ovarian Cyst, Complicated by Appendicitis and Distended Gall-bladder.—Dr. C. C. Sichel reported this case. The patient was twenty-seven years old, a general houseworker, married, and gave a negative previous history. On September 30, 1907, the patient was suddenly seized with sharp, stabbing pain in the abdomen which was accompanied by a severe chill and fever, lasting about four hours. This passed off, but a second attack occurred on October 1, lasting twenty-four hours. The patient was admitted to the hospital on October 2, complaining of pain and tenderness. Her temperature was 99°, pulse 100, and respiration 32. There was some abdominal rigidity, but no tympanites. There was considerable pain over the right side of the abdomen. A diagnosis of small cystic ovary was made, complicating an appendicitis. At operation a slightly cystic ovary was found on the right side, which was removed. The appendix was found to be swollen and congested, with a few adhesions and a beginning infection. The appendix was removed. The gall-bladder was found to be distended and very tense; on further examination this tension was overcome and, as no stones were felt, the abdomen was closed and the patient made a complete and rapid recovery.

Dr. Eugene C. Savidge called attention to the fact that Dr. Sichel's first patient began to lose weight June 1 and entered the hospital September 1. This had a direct bearing upon the paper of the evening.

Case of Inverted Appendix, Reoperated, with Microphotograph.—Dr. Henry Dawson Furniss presented this specimen. The patient from whom the appendix was removed was a woman, forty-five years old. Six years ago she had an abdominal section when plastic work was done on the tubes and ovaries and the appendix was inverted after the method of Edebohls. Two years ago Dr. Furniss did a cecostomy for a mucous colitis in order that the whole of the large intestine might be irrigated. The operation was done in the same manner as a Kader's gastrotomy, the cecum being sutured to the parietal peritoneum, and a permanent catheter being left in the cecal opening. On December 23, 1907, to close the fistula, he cut down the cecum, separated it from the abdominal wall for an inch around the opening, the edges of which were then freshened. At the lower angle of the cecal opening was the appendix, projecting three-quarters of an inch into the cecum. This with its base was removed, and the cecal fistula closed. The microscopic section of the appendix showed nothing abnormal other than the inversion. From without inward was seen the mucous membrane, the submucosa with lymphatic tissue and lymph nodes in places, circular muscular layer, longitudinal muscular layer, and in the center a "core" of fibrous tissue. The blood-vessels were in the submucosa, but were more numerous and larger in the inner fibrous "core," representing the serosa and subserosa. It was claimed that often a portion of the appendix in these cases sloughed away, leaving a stump of from a quarter of an inch to more in length. Unfortunately, no longitudinal sections were made of this specimen to determine whether it was a stump, or only an appendix shortened longitudinally. From the clinical history of the patient he did not think that the inversion of the appendix had anything to do with the mucous colitis, for the colitis was present before the appendix operation and was no more severe afterwards. As the colitis had almost cleared up at the time the appendix was removed (second operation), it could not be said that the excision of this organ had any bearing on her subsequent history.

Dr. John O. Polak said that he had seen a number of cases of colitis subsequent to the operation of inverting the stump of the appendix.

Dr. Furniss did not believe that there was any relation at all between the inversion of the stump of the appendix and the mucous colitis. This patient had, however, a complete achylia gastrica, and had been on a vegetable diet with marked improvement of that condition.

Case of Operation Upon the Cervix Under Hypnosis.—Dr. Chas. F. Adams reported this case. The patient was forty-six years old, married twenty years, had three children and one miscarriage shortly after marriage. The last child was born ten years ago. Her first two confinements were normal and fairly easy. The third was very hard, and from that she dated her trouble. She had a great deal of headache, referred principally to the occiput, and some backache. She had quite a profuse leucorrhea. She had had occasional local treatments during the past seven years. An examination revealed a stellate tear of the cervix, very deep on the posterior lip, and extending directly backward, suggesting malignancy. The cervix was amputated on November 20, 1907, under hypnosis. The patient felt no pain whatever. Dr. Adams noticed that there was less relaxation of the parts and more hemorrhage when operating under hypnosis.

Dr. William S. Stone asked that Dr. Adams describe the technique of hypnosis more in detail, as well as the details immediately following operation.

Dr. Adams acknowledged that he had but little faith in hypnosis. Dr. Leonard, who applied this method, was now out in the West developing a gold mine. The patient was under operation for one hour. Hypnosis was applied one-half hour before the beginning of the operation. During the operation Dr. Leonard stood at the patient's head and mumbled something to her like "feel no pain; feel no pain." Although Dr. Adams had but little faith in hypnosis, he was surprised at the patient being so long under the knife and experiencing no pain whatever. In order to test the sensibility, he ran the needle into the perineum once or twice, but the patient did not budge. The hemorrhage was more profuse than ordinary.

Dr. Henry Dawson Furniss said that two years ago he had a patient, a young, undeveloped girl, who had persistent retching. He was able to put her to sleep in twenty minutes by suggestion; he kept her asleep twenty-one hours out of the twenty-four. At last he taught the family how to use hypnosis. She had a cyst of the ovary, and Dr. Edebohls, Dr. Polk, and others examined her while she was under hypnosis without giving any pain or causing any spasm. After she was operated on, she developed a cystitis from the use of the catheter. She was cystoscoped, and the ureters were catheterized without any pain whatsoever under hypnosis. Dr. Furniss said he had employed hypnosis in two other people, but had failed in others. With regard to hemorrhage in cervix operations, he had gotten most perfect hemostasis by using adrenalin 1-6000.

Dr. Stone asked where he injected the adrenalin.

Dr. Furniss replied that he injected it under the mucous membrane covering the whole area he intended to dissect, using not more than forty minims.

The Cancer Problem.—Dr. Eugene Coleman Savidge read this paper. (See page 717.)

Dr. Eden V. Delphey said that when the living body was subjected to the action of radioactivity either from the *x*-ray or radium, the cells, whose equilibrium was most unstable, were the ones first and most acted upon. These cells were the stratum granulosum of the skin, the endothelia of the blood-vessels, the lymphocytes, the cells of the glandular system, the cells of the nervous system, and those of neoplasms. This effect was produced in three different and distinct stages, viz, by stimulating to increased normal metabolism, by increased stimulation to erratic neoplastic growth, and by overstimulation to death and disintegration of tissues, either microscopical or en masse. One reason why the *x*-ray failed in the treatment of deep-seated neoplasms was that, while it might destroy the superficial portion, at the same time because the radio-resistance of the tissues weakened the effect of the rays, the deeper parts were stimulated to increased malevolent growth. As radium was inserted directly into the body of the neoplasm and its action was directly from within outward toward the circumference, and as it had a selective action upon the erratic cells, better results might be hoped for and obtained, provided the dosage could be so adjusted as to destroy the malignant cells and not stimulate the normal ones to erratic neoplastic growth.

Dr. Herman J. Boldt said that Dr. Savidge was probably under the impression that cancer was a systemic disease rather than a local one; that was the import he gained from listening to the paper. If carcinoma was a systemic disease it was difficult to understand how these sufferers were to be cured. If these neoplasms were attacked surgically in their early stages, frequently they could expect a radical cure. For instance, so far as carcinoma of the uterus was concerned, permanent cures might be expected in twenty-two per cent. of the cases operated on radically. On the other hand, a question was brought up in regard to cachexia; cachexia was a preliminary stage of cancer, and Dr. Boldt said he had yet to see a case of marked cachexia and the patient successfully operated on. There was not a single instance on record of a cure of cancer by operation when cachexia was present because of the neoplasm. Dr. Boldt had no doubt but that in time the cause of cancer would be discovered and its cure accomplished, and it might be along the lines Dr. Savidge outlined. The systemic condition of cachexia was consequent upon the local focus of disease.

Dr. Savidge closed the discussion.

Philadelphia Pediatric Society.

At a stated meeting, held April 14, Dr. Alfred Hand, Jr., exhibited a group of cases of "Heart Disease in Children." In some there was a previous history of rheumatism or chorea, while in others there was a history of some other infectious disease. In one the finger ends were clubbed, and an *x*-ray picture showed that the enlargement involved only the soft tissues, and not the bones. Dr. Arthur Newlin presented a case of "Brachial Palsy, Due to Compression by Forceps During Labor." The Patient was a child six weeks old, with total paralysis of the entire right upper extremity. Labor had been difficult and prolonged, and delivery was instrumental. After birth, there was paralysis of both upper extremities, but that on the left side soon disappeared, while that on the right persisted. Drs. S. McC. Hamill and Howard C. Carpenter presented a group of children, exhibiting the "Calmette, von Pirquet, and Moro Cutaneous Reactions for Tuberculosis." For instillation into the eye a ½ per cent. solution of tuberculin was employed, for subcutaneous inoculation a 10 per cent. solution, and for inunction a 50 per cent. ointment in wool fat. There was a certain parallelism in the reaction obtained by all of these methods. Instillation into the conjunctival sac was followed in cases presenting a positive result by redness, and, injection involving not only the conjunctiva itself, but also the semilunar fold and the caruncle. Subcutaneous inoculation gave rise to circumscribed inflammatory phenomena, while the application of the ointment to the skin was followed by the development of papules and vesicles on an erythematous base. The ocular reaction is not wholly without danger, phlyctenular keratitis, with ulceration, occurring in some of the cases submitted to the test. Dr. A. Parker Hitchens read a paper entitled "Anaphylaxis." He defined this condition as one of lessened resistance and increased susceptibility to the action of toxic substances. It has been shown that the introduction of small amounts of serum or of proteid from an organism belonging to one species into the circulation of an animal belonging to another species gives rise to a condition in which a second injection of the same substance in much less than the minimum lethal dose gives rise to speedily fatal results. This termination can be averted in some animals by practising ether narcosis before the second injection is made. A demonstration of these facts was made. Dr. B. Franklin Royer read a paper entitled "Hypersusceptibility to Horse Serum in Man." He cited a number of instances in which when second injections of diphtheria antitoxin were given to children toxic symptoms developed, as manifested by elevation of temperature, articular swelling, urticarial, and other cutaneous exanthems. Fatal results in man have never taken place after such second injections, the small number of deaths following antitoxin injections having resulted from primary injections, and for these an explanation is as yet wanting.

College of Physicians of Philadelphia.

Section on General Medicine.

At a stated meeting held March 9, Dr. E. Franklin Stahl exhibited "A Case of Probable Acute Lymphatic Leukemia." The patient was a boy about twelve years with marked pallor, distended abdomen, enlarged super-

ficial glands, enlarged spleen, enlarged liver, elevation of temperature. There was some interference with the entrance of air into the main bronchi, probably from the pressure exerted by enlarged lymphatic glands at the roots of the lungs. The differentiation was to be made from pseudoleukemia by means of a study of the leukocytes. It had, thus far, been possible only to make an estimation of the hemoglobin percentage, and this was found to be 30 per cent. The condition had not been noticed for more than six weeks.

Dr. J. Alison Scott exhibited "Two Patients Having Thoracic Aneurysms." One of these was an Italian, 65 years old, with a good family and personal history, who had complained of pain in the right chest, extending down the corresponding upper extremity. The veins of the anterior aspect of the chest and abdomen were enormously dilated and tortuous. Under rest and medicinal treatment the pulsatile tumor visible on the anterior aspect of the chest diminished in size, yielding dullness on percussion, and the expansile quality of the pulsation disappeared. The second patient was a colored man who for a time received relief from the operation of wiring and the passage of a galvanic current. Subsequently, however, the symptoms returned in aggravated degree and the tumor underwent increase in size. Dr. Scott exhibited also "A Specimen of Aneurysm Treated by Wiring and Electrolysis." In this case the patient lived for a couple of weeks after the operation and died, not from hemorrhage as a result of rupture, but from acute heart failure.

Dr. George W. Norris exhibited "A Patient Having an aneurysm of the Thoracic and of the Abdominal Aorta." Drs. J. C. DaCosta, Jr., and J. G. Beardsley presented a communication entitled "The Resistance of Diabetics to Bacterial Infections." The paper was based on a study of the opsonic and phagocytic indices in cases of diabetes mellitus, as compared with those in cases of diabetes insipidus, transitory nondiabetic glycosuria and in healthy persons, and it was found that the resistance to tubercle bacilli, to streptococci, and to staphylococci was distinctly lowered, as indicated by a lowering of the indices mentioned. Dr. R. Max Goepp read a paper entitled "A Case of Typhoid Fever Ushered in by an Attack of Uremia." No history of previous nephritis could be obtained and it was only after the symptoms of uremia began to subside that the diagnosis of typhoid fever became clear.

Diagnosis of Slight Cases of Scarlatina.—J. Deshaves says that scarlatina is frequently so slight that the symptoms are almost nil. There is an enanthem involving the boccopharyngeal region, an ephemeral eruption, and a desquamation of the tongue especially, preceding that of the skin. The lingual desquamation is the only characteristic point. It begins at the tip, there being a thick white coat, and extends toward the back of the tongue, leaving a red surface with prominent papillæ. This is the most characteristic symptom, and in its absence we cannot enforce quarantine. Vomiting is slight and like that of indigestion. The eruption is so slight and evanescent that it often appears and disappears in a night. It appears only on the chest, abdomen and back, and being covered by the clothing is not noticed by the mother. The fever is often very slight, and the sore throat not at all marked. But the tongue generally shows some characteristic signs. —*Le Bulletin Médical de Québec.*

Functional Relations of Fetal and Maternal Thyroids.—Giuseppe Fossati has observed a number of cases of thyroid enlargement in the mother during pregnancy in which the child at birth also showed enlargement of the thyroid. He believes that the thyroid does not functionate during intrauterine life. Only in exceptional cases does any function take place. These are cases in which disease of the maternal thyroid rendered it necessary to the welfare of the child while in the womb to have the thyroid secretion. In these cases such function does take place and the gland becomes enlarged. This enlargement disappears soon after birth. In other cases the enlargement of the thyroid seems to be an hereditary condition, and such thyroids do not decrease after birth.—*Annali di Ostetricia e Gynecologia.*

DARWINISM AND DIABETES.

By R. G. ECCLES, M.D.,

BROOKLYN, NEW YORK.

In this year of grace, 1908, it would be a difficult task to find a biologist who is not an evolutionist. This does not mean that they all accept natural selection as the all-in-all of evolution, as do the Neo-Darwinians. The majority, however, believe with Darwin that the principal moulding force, and the one that has brought organic nature to its present condition of perfection, is the selecting one. As invariably occurs with all changes in belief this acceptance of Darwinism, in whole or in part, brings with it the necessary acceptance of far-reaching logical conclusions that must control ideas, regulate conduct, and direct research, in ways not at first contemplated in the change. It may seem a far cry from Darwinism to diabetes, but it is, nevertheless, one of extreme importance and great significance. Along with it go many other of the profound effects of selection ideas on medical science. We see relatively few of these to-day as compared with the overwhelming predominance that Darwinian ideas are likely to have on the medicine of the future. The sooner medical men follow botanists and zoologists into evolutionary methods of thought the better it is likely to be for their patients. The struggle for existence is a never-ending struggle against privation and disease. The struggle against privation is, itself, a struggle against a predisposing cause of disease. It is therefore apparent that *nothing in nature is more closely associated with every form of evolution than is disease.* All along the whole line of organic development the fit that have survived to people the earth have been those that have triumphed over disease and death in this fierce struggle. Every selected organic change has been one in which nature has acted as the physician and the change has been the remedy. Maladjustment, in an organism, always means physiological derangement —or perhaps it would be better to say rearrangement—and the resulting death, whether due to hunger, injury gained in struggling for the means by which to avoid hunger, or by direct bacterial or protozoan invasion, is invariably associated with disease. It needs but a momentary contemplation of any organism for an intelligent physician to perceive that it is defended at every point by some more or less effective protective appliance—protective against microorganisms. To a consistent believer in natural selection these can all have but one meaning. They are there because they have been selected as life saving. They are survivals in past struggles against disease. Their adaptiveness is evidence that the organisms possessing them have survived through such possession. But for these they would not be on the earth for us to study. Had not their forebears again and again, through millenniums of time, faced and baffled disease no such complex series of protective appliances could have been acquired. An accident might bring one, but such a connected and coordinate chain of them could not have arisen fortuitously. Either they were designed by a Supreme Mind or they have resulted from innumerable selections and been preserved together by heredity. No third alternative is thinkable. To the consistent Darwinian these defenses are what is left of battles waged against disease through past eons of time. Every physiological response of the body is part of the complex of fitness. The response to injury and to microbic invasion is as much an adjustment to the requirements of the organism as is that to hunger. The healing forces are as truly physiological as are those of assimilation and growth. To the consistent evolutionist pathology is no more and no less than readapted physiology. The plasticity and the reserve forces are, equally with the daily active forces, physiological. To some physicians this may savor of novelty, but to those who are keeping abreast of biological thought and discovery it will appear as but the statement of a most elementary principle. But it is not all of those who have unreservedly given adherence to this view who are willing to be as outspoken, frank, and unflinchingly logical about it as has been Sir Frederick Treves, Surgeon to his Majesty, Edward VII, of Great Britain. In the Inaugural Address before the Edinburgh Philosophical Institute, in 1905, he created no small amount of commotion by the emphatic way in which he presented this conviction. In words that are certainly free from any suspicion of equivocation he declared that "the processes of disease are aimed not at the destruction of life, but at the saving of it," and that "if it were not for 'disease' in the popular sense the human race would soon be extinct." He then went on to say that "for centuries there has been presented the strange spectacle of men of science struggling to the utmost to thwart, to curb, to annihilate a process of cure."[1] Unfortunately for the ailing, this strange spectacle is far from having ceased, although in one or two instances it has been checked. Those who persist in this strange spectacle are utterly oblivious of the fact that they are doing so and would probably indignantly deny that they are doing anything of the kind. In an interesting paper, entitled "Medicine Old and New," written by Dr. W. H. Dickinson, and published in the *Lancet*, we find the following reference to this same strange spectacle: "Nature and the physician played the part of the Government and the Opposition; whatever one did the other opposed. If purging occurred in the course of cholera, obedient to some natural law whereby poisons

are expelled, the physician was ready with his opiates and astringents to forbid the discharge. We have not to go back many generations to find that there were those who forbade water in cholera for no other reason which is known to us than that nature called for it by creating thirst."[2]

That there are limits to the power of nature to adapt itself to disease it would be foolish to deny. Natural selection has not yet brought complete and perfect adjustment to every kind of disease and injury. Where its opportunities have been inadequate we still have maladjustment. Only in cases where organisms unprepared to respond favorably have been destroyed is selection effective in bringing new or extending the power of old adjustments. Disease, favorable variation, and adequate selection are all necessary factors in enabling an organism to make a good response to an invasion of pathogenic microorganisms. As a consequence we have to deal with some "blunders of nature." Dr. Welsh, of Johns Hopkins University, states this idea in these words: "The agencies employed by nature may be all that can be desired; they may, however, be inadequate, even helpless, and their operation may add to existing disorder."[3] They are adequate where, in the past history of the species, they have been of sufficient selective value to survive during a reign of that or a kindred disease. They are inadequate, and may be injurious, where they lie outside the limits of selected adaptations. Future research will enable us to trace out the exact limits of these adaptations and inform us exactly to what extent and where it is wise for the physician or the surgeon to interfere. In the case of thirst in fever, so general is this demand that it would be absurd for an evolutionist to attribute it to chance, and still more absurd for him to class it as malevolent. To the disbeliever in evolution it may signify nothing or may mean anything according to his type of cosmogony. If it occurred only as an occasional event, in an occasional patient that suffered from fever, no evolutionist could consider it as being, with certainty, a useful response. Its constant association with fever, and its constant association with the needs of the body in health, are evidence of its having been selected and therefore beneficial. Experience has confirmed the view that it is beneficial in disease as well as in health. It meets a tissue want. Inflammation is an equally general response to injury, in all of its principal features, so that the consistent evolutionist must consider it conservative and more or less curative. Concerning it Prof. J. George Adami says: "Taking as our definition that inflammation is the response or reaction to injury, we are inevitably led to see that this response results in counteracting, or, more exactly, intending to counteract, the deleterious effects of the irritant; the inflammatory process tends toward repair. It may not result in repair, for, as we have pointed out in several instances, too often the reaction is either inadequate or excessive."[4] The rule is for injuries to heal and the exception for them to fail to heal. Each exception is a case in which the introduced irritant is excessive in potency within a narrow area, or excessive in quantity over an extensive area. In either case it is one that exceeds the curative power that natural selection, through heredity, has bequeathed. A multiplication of such cases, over a long period of time, would either extend the limits of the healing power or the species would disappear. Here a response of acquired vigor, through a favorable environment, would give the advantage needed, without a variation in the germ plasm.

We now come to the consideration of one exceedingly general reaction of organisms toward adverse conditions, that few medical men have attempted to interpret as conservative and beneficent. The present attitude of almost the entire profession toward it is pre-Darwinian. I refer to hyperglycemia and glycosuria. The same hopelessness now exists regarding these as existed regarding inflammation, fever, and thirst, when they were looked at from the same viewpoint. The presence of an unusual amount of sugar in the blood and its appearance in the urine is deemed a maladjustment. Almost the entire profession is of the opinion that the body, somehow, is at fault in permitting this apparent waste. To few or none has the idea suggested itself that this excessive outpour of sugar may be an attempt on the part of nature to remove some obstruction, cure some injury, or rid the body of some irritant. There are those who feel quite certain that an excessive use of sugar has established and is continuing the trouble. There are still others who hold that the real derangement is due to the body having lost its power to oxidize sugar. We learn that so high an authority as von Noorden "likens the giving of carbohydrate food to a diabetic to the pouring of water into a cracked vessel."[5] All have sought to reduce the amount of dextrose in the blood and some have gone to such an extreme that they have about starved their patients. Every effort of treatment, of explanation, and even of scientific research, has been prejudged and predirected by the assumption that the hyperglycemia is an evil to be curbed, a misdirection of nature to be readjusted. There has been no sober weighing of the facts under the hypothesis that it may be a blessing to be encouraged, an effort at cure not to be frustrated. The fact of our knowing that we do not know what the real trouble is has not appeared to hold us in that truly scientific mental condition of suspended judgment that eagerly seeks to "prove all things." Since the days of Susruta, the seventh century Hindoo who first called attention to the sweetness of diabetic urine, and since the time of Thomas Willis, who, in 1674, rediscovered the same fact in England, what new thing, except Dr. Dobson's chemical proof, in 1775, that the sweetness is really due to sugar, has clinical experience or scientific research taught us about diabetes mellitus? Bunge informs us of the fact that: "This is a subject which touches on all branches of physiological chemistry, and about which a complete library of books has been written, the references to which would alone form a good sized volume."[6] If diabetes is not the most written about subject in medicine it is certainly one of the leaders in this direction, and yet it is the one concerning which the same author says: "Up to the present pathological anatomy has led to no conclusion."[7] Concerning it Dr. Osler declares: "We are ignorant of the nature of the disease."[8] Dr. W. H. Thomson, of New York, tells us that, "with glycosuria we do not know whence it cometh nor whither it goeth; and, therefore, we can never be sure what its significance is."[9] With *"Ignoramus"* thus written in bold characters over it how long shall we remain willing to keep pushing our investigations along this old, non-remu-

nerating road? As if to give a proper finish to the whole Prof. Lusk assures us that "there is no known cure for diabetes."[10] Alas! All this is only too true. Generations of clinical experience with over half a century of original research have proven fruitless. Does it not seem as if it was nearly time to face around, give up the evidently false cues that we have been following, and try a new, untrodden road? Past experience, with fever and inflammation, ought to have rid our minds of the obsessing notion that any general symptom of a disease is an evil to be curbed. Why not try the Darwinian idea, for a while, and assume that the sugar is being wasted as a physiological reaction to overcome some present irritant of exogenous origin? If we scan it for a brief period from this viewpoint we will immediately be astonished at the determined way in which the bodily energies seek to supply that excess of sugar and seek to dam it back in the circulation. Every energy of the body seems as if called upon to accomplish this task, and as if life itself depended on their doing so. Every power of synthesis and of analysis at the command of the forces of metabolism is called into play in order to produce dextrose. The nervous system, the glandular system, the circulatory system, each and all work to this end.. Ordnance and gunpowder are no more in demand during the invasion of a country by an enemy than is the demand for dextrose by the entire bodily energies. Everything in the form of food that is supplied is worked up into dextrose. Even in the case of proteid, in which the conversion is a roundabout one, and the expenditure of energy must be great, dextrose is the product aimed at. When the supplied food is at an end the tissues at once proceed to the work of converting every cell reserve into dextrose. Prof. Lusk informs us that "It has long been known that diabetics eliminate sugar even after all administration of sugar has stopped."[11] Prof. Wells tells us that "This hyperglycemia is remarkable in that, at least in the advanced stages of diabetes, it persists even when the patient is receiving no carbohydrate whatever in the food."[12] Prof. Tigestedt says that "In the severe forms of the disease, to which pancreatic diabetes belongs, sugar appears in the urine even if no carbohydrates are given in the food."[13] Prof. Bunge declares that "the excretion of sugar continues, even though an exclusive meat diet be adopted."[14] The same author also states that "It was proved, by careful experiment in three severe cases, that the patient excreted more nitrogen than a healthy person on exactly the same diet."[15] It would thus appear that even the tissues are drawn upon in order to keep up the supply. If all this is perversion of function and merely aimed at keeping up a hopeless and fruitless waste, then nature must have bungled badly in her selections. For what would appear, from a reasonable interpretation of the facts, to be countless millenniums of natural selection, nature has failed to discover a correction of this evil. If the excess of sugar is of no use in the blood how came all of the organs to be working together to keep it there? Does natural selection ever work toward the accumulation of correlated maladjustments? If it does in this case then there is no reason for assuming that it does not and cannot do the same elsewhere. That it should or could do such a monstrous thing is utterly unthinkable. That would be equivalent to saying that it causes the unfit to survive while destroying the fit, which is a preposterous absurdity. Let us, for instance, take into consideration the case of the kidneys. Von Noorden says: "Let us think for a moment of the quantitative relationships. If we find 0.2 per cent. of sugar in the blood, that is already a respectable degree of hyperglycemia; in the total blood in the body there would be some 5 or 6 grams of sugar over and above the normal. The kidneys, if they were working normally, could easily rid the blood of this in less than one hour. But they do not do so. . . . There should be no such sugar accumulation in the blood if the kidneys were properly performing their function."[16] It did not seem to occur to Prof. von Noorden that this holding back of an extra amount of sugar might be a display of reserve physiological effort for the purpose of aiding that sugar as a curative agent. In bad cases they hold or dam the sugar back in the blood to the extent of 0.44 per cent.[17] Not only do they persist in keeping this sugar back but they do so in defiance of the most potent diuretic treatment. Von Noorden further informs us that:

"In diabetes the kidneys maintain their impermeability to sugar in the face of strong diuretics, even against the urine secretion called forth by theobromine and caffeine. In edematous patients suffering from severe diabetes these drugs often increase the volume of urine only, and do not influence the total quantity of sugar passed. I have several clinical examples of this."[18] To see this from the viewpoint of its being an effort at cure is to make it at once quite explicable. To view it in the opposite light is to be compelled to write it down a mystery. If the sugar is needed in the blood, in increased amounts, this action of the kidneys is seen to be a perfectably reasonable and useful one. If it is thus needed we can easily understand why the nervous system should establish conditions leading to the decomposition of the stored glycogen into dextrose. If needed there we cannot wonder at all the available chemical forces of the body being called into requisition for the purpose of manufacturing dextrose from anything and everything that they can attack. If that dextrose is all made to be wasted, regardless of adaptation to any useful purpose, something must be wrong with nature. It would have been bad enough in a breakdown of the physiological forces had the work in regard to sugar been lessened or stopped, but for every available power to be forced into line to supply this superabundance and to dam it back to the further injury of the organism is something that looks wonderfully diabolic.

Hyperglycemia is one of the most common of disease and internal injury symptoms. The English authority, Dr. Saundby, says: "The list of the immediate causes of diabetes is a very long one, but in most instances the relationship reposes on too well established a basis of clinical evidence to be rejected. . . . In the first place comes the long catalogue of injuries, such as railway accidents, severe contusions of the head, spine or abdomen, violent musular strains, and lightning stroke. . . . Numerous well attested examples have been regarded as sequels of enteric fever, diphtheria, tonsillitis (?), influenza, acute rheumatism, malaria, and syphilis."[19] Von Noorden tells us that, "Besides gross mechanical lesions certain poisons have

the power to produce glycosuria in animals. I may mention CO,CS_2, curare, morphine, strychnine, nitrobenzol, amyl nitrite, uranium salts, salts of mercury, hydrochloric and sulphuric acids, various narcotics, and preparations of theobromine and caffeine. The number grows larger every year."[20] It almost seems as if hyperglycemia inwardly served the purpose of serum to external slight injuries. Professor Lusk tells us that, "Hofmeister has discovered that the fasting organism is more susceptible to alimentary glycosuria than the well-fed one."[21] Since a fasting organism is more susceptible to attacks from pathogenic microorganisms than a well-fed one we would, on evolutionary grounds, expect this to be the case. If the sugar is protective, in any way, what more natural than that it should be poured out, by every animal after fasting, if the slightest degree of bacterial attack has occurred. If the sugar is not protective, and worse still if it is injurious, then its appearance after fasting is unexplainable. Here, too, we are reminded of the fact that in "diabetics during complete starvation sugar continues to be secreted in the urine in considerable amounts."[22] We are forced to inquire why, if the sugar is an injury, the cells, at the expense of their own substance, thus pour it out? Why do they manufacture sugar, out of that which is not sugar if it is an injury to them? Here is an apparently deliberate turning out of their way to do that which is said to be damaging. But hunger is not the only thing that is known to lower vital resistance to germs. Cold will do the same. Dr. Saundby tells us that "exposure to severe cold, and the ingestion of cold food (ices) or iced drinks"[23] is among the causes of glycosuria. A most remarkable thing about this action of cold is that it not only causes the pouring out of an excess of sugar into the animal circulation but it does the same in the vegetable world. Pfeiffer says: "It seems *very commonly* to be the case that when exposed to cold, plants contain a larger proportion of sugar."[24] (Italics mine.) Elsewhere the same author tells us that, "The fact that cold acts as a stimulus inducing an increased production of sugar in many plants is of great biological importance."[25] It is a well known fact that many kinds of seeds contain a glucoside associated with an enzyme so that immediately the seed is injured in the presence of dampness, sugar is formed to bathe the injured surface. Bunge tells us that when animals are chilled, experimentally, they convert their glycogen into an increased supply of sugar.[26] It is thus seen that practically all of animated nature reacts to the depressing effects of cold by a hyperglycemia. Just as the external injury of a plant is bathed by its healing juice so an internal one is treated by an extra supply of sugar. Just as an external injury in an animal is treated to an outflow of serum so an internal one is treated to an extra supply of sugar. There is still another common cause of reduced resisting power in animals, and that is fatigue. Here again the vital forces respond with a hyperglycemia. Surely so general a phenomenon must be replete with meaning and must, through millenniums of natural selection, have been thus saved through being of service to all forms of life. The evolutionist is constrained to say with Pfeiffer that it must be "of *great* biological importance." If it is a menace to life then we must conclude that nature has been badly put together.

A quarter of a century ago, when the writer was beginning the practice of medicine, all the text-books assured us that the proper way to treat cases of glycosuria, of every kind, was to withdraw all carbohydrates possible from the diet. The dextrose was considered the demon of diabetes, and every case of glycosuria was a case of diabetes. Since then many of us have learned, to our cost, that a rigid exclusion of carbohydrates is scarcely a proper proceeding. For some reason current theory has not been found to agree with the possibilities of practice. This, however, does not seem to deter authors from still advising what they are pleased to call "careful dieting." It would be rather difficult to know, at present, just what is meant by this expression. It has become exceedingly elastic in meaning. In "Diet and Disease" we are told that "careful dieting may prolong life and prevent the onset of complications. In these cases the carbohydrates are of no value as food, but they may be allowed now and then to satisfy the patient's craving for them. In order to check the glycosuria, not only the carbohydrates must be discontinued, but the amount of protein also must be reduced."[27] The authors just quoted do not seem to be aware of the fact that Kulz has shown that "in severe diabetes there is a smaller amount of sugar in the urine than would correspond to the carbohydrate of the food."[28] It is not, therefore, true that the "carbohydrates are of no value as food." The statement that the carbohydrates "may be allowed now and then to satisfy the patient's craving for them" reminds one very much of the time when soft-hearted doctors relaxed their stubborn rules sufficiently to let fever patients have a little water "now and then to satisfy the patient's craving" for it. We have already seen that if a diabetic is starved he will use up his bodily tissues in order to get sugar for the circulation. Is it not then rather hard on patients to restrict even the proteid, seeing that it means that the patient will get his excess of sugar anyway? It practically means a hastening of his death. All recent work on the physiology of assimilation has been teaching us that every change the food undergoes, from the mouth to the cell, is brought about by a connected series of stimulations. Each step introduces a stimulation that brings about the next step. The evolutionist cannot avoid seeing in this a linked mechanism that has resulted from ages of successive selections. Hunger and thirst are the beginning stimulations that compel the animal to supply the stomach with food and drink. Every person knows that there are many kinds of hunger having selective power over various kinds of food. The hunger for fat is quite unlike the hunger for bread. The hunger for bread is not to be confounded with the hunger for meat. We have a multitude of choices in the many stimulating flavors. One carbohydrate may, for a while, satisfy the longing for carbohydrates in general, but let any person try to live for a while in Japan, on Japanese food, and he will soon feel an intense craving for bread that nothing else can assuage. Until he gets it, every meal will leave a longing void. There is a choice, by the stomach, from among proteids, and likewise a choice from among fats. What the cells have adjusted themselves to the stomach calls after. If they need water they never call for sugar. If they need fat they do not call for sugar, although able to convert that

sugar into fat. The unbroken chain of successive stimulations is thus seen to be selective. Let that chain be broken, and then, instead of a call for a given type of food there comes first an indifference to it and later a repugnance. An excess of any one kind of food brings a sense of disgust toward that food. In various conditions of disease we refuse to eat certain kinds of food because we "turn against it." In extreme sickness the connections with the cells are all severed, except, possibly, for water. If, in diabetes, the connection between cell and sugar is severed we should expect a loss of desire for sugar and for the usual sugar-producing substances. Instead of this, however, we find the reverse. There is an increasing longing for carbohydrates, just as there would be if more was needed than was being supplied.

One of the most comical features connected with the tragedy of diabetes is the new attitude of the no-carbohydrate advocates in regard to cures for this affection. In the same work in which students have been told that "not only the carbohydrates must be *discontinued* but the amount of protein also must be reduced" we learn that "Mossé first advised the potato cure as a means of treating patients suffering with diabetes. His plan is to replace all carbohydrates by potatoes for a period of several weeks. . . . Mossé found a marked diminution in the glycosuria and polyuria while the patient was taking the potato starch, as well as a diminution in thirst and an increase in strength. . . . Offer has confirmed the observation of Mossé and von Noorden, too, extols this plan of treatment." [29] To the writer this looks like an unconditional surrender and that nature has whipped them into line by hard blows. Like the "fiction" in law they believe in keeping a wordy consistence with their past record but at the same time getting into full line, in practice, with progress. If the carbohydrates must be discontinued, where the patients themselves direct, the doctor must prescribe for them, as medicine, a food containing over 75 per cent. of carbohydrates, when its water is excluded. Using carbohydrate as a cure and forbidding it as a food looks a bit inconsistent. It would not be at all surprising to soon hear of a bread cure or even of an arrowroot cure. A recent verdict, however, on bread is that "It is the *bête noire* of diabetic diet. The patient, whatever his indifference to bread while in health, immediately acquires an irrepressible longing for it when it is interdicted. The ordinary white wheat flour contains 85 per cent. of starch and it is unfit food for a diabetic." [30] If potatoes have proven to be a good "cure" for diabetes it is hard to understand how bread can be so bad. It has a little more starch, it is true, but the difference is so slight that it could easily be overcome by a slight dilution of the flour as, for instance, giving Graham bread. The "irrepressible longing," which it took ages of natural selection to establish, evidently means nothing but whim to those obsessed with ancient notions.

In a report on the Progress of Medicine, in the *New York Journal of Medicine*, we are told that: "The sudden and complete withdrawal of carbohydrates from the diet of a diabetic patient is known to be dangerous." [31] Dr. W. H. White, of Guy's Hospital, London, states that, "too sudden a deprivation of carbohydrates may lead to coma." [32] It thus would appear that a change which suddenly lowers the sugar contents of the diabetic's blood tends to hasten coma and death. When the system is given time to produce sugar from proteid and to thus keep up the hyperglycemia no such calamity befalls. The work of tearing down the proteid and then reconverting it into dextrose requires time and effort on the part of the cells. During the delay of readjustment the body suffers and the patient becomes comatose. This forcing of the system to use proteid where carbohydrate is required is, itself, a sort of superimposed disease upon the diabetes. It necessitates a derangement of normal metabolism just as a disease does. The response to the enforced change in diet, like disease responses in general, is only possible because of the reserve power that natural selection has provided. Like all substitutes for normal processes, however, it has serious limitations. That this is so is seen in the fact that "A diet consisting exclusively of proteid is objectionable, because it gives rise to acetonuria and increases the danger of coma." [33] Even von Noorden acknowledges this fact when he tells us that, "Hirschfeld attributed acetonuria in febrile states to defect of carbohydrate in the food taken, and, as a matter of fact, febrile diaceturia and acetonuria are often observed to diminish after the administration of carbohydrates, as is also to be noted in acetonuria attending starvation or a diet of animal fat." [34] Can the unbiased reader take in such facts as these and not become suspicious of past lines of treatment as having been the very things that produced the dangerous and appalling symptoms that have all along been attributed to the sugar? The supplying of carbohydrates stops the coma, the taking of them away from the patient produces it. The carbohydrates of potatoes add strength and vigor to the sufferer and make him feel well. Diabetics, like normal human beings, can get along well only on a normal diet. An abnormal one only adds an artificially produced disease to the diabetes thus giving him two diseases to fight instead of one. To crowd upon them a diet that would make a well man sick is only to make a bad matter worse. Since they require dextrose to maintain bodily energy, the same as other mortals do, why put the system to the extra strain of synthetizing that dextrose from protein? Even if at the expense of great drain through the kidneys, since the bodily energies insist upon that way of doing things, the waste is less if the dextrose is supplied in the most easily available form. The claim that the body is incapable of using the dextrose when supplied has no bearing on the subject. The entire effort of the body is bent toward keeping it there, and we have already seen that more enters as food than passes off in the urine, even in severe cases. Let us now consider another fact having a bearing upon this. Dr. W. H. White, whose paper we have already quoted from, says: "We want an explanation of the strange disappearance of sugar when coma comes on. This may be of great practical importance." [35] That it is of great practical importance none will doubt when they have begun to view the problem from the Darwinian viewpoint. It means, and can mean nothing else, that in the collapse of the body the effort to hold a large amount of sugar in the circulation is withdrawn and glycolysis proceeds, unhindered. The physiological effort at saving the body from the impending danger of the real cause of the diabetes

is compelled to end by the more imminent danger of the coma perhaps brought about by false feeding. The engine of metabolism having been switched into the side track of proteid conversion is compelled to rush back into the true track, in order to avoid destruction of the entire body. The danger along the true track has become less than is the danger in the switch. Let us now, for a while, reconsider the danger that is supposed to exist in the sugar itself.

When the unknown irritant that is the real cause of diabetes shows no immediate signs of a hastily fatal termination how much harm does the sugar produce? Dr. Saundby says: "I have recorded an instance of persistent glycosuria in a man who appeared quite healthy, and at the present time, eight years after I first found sugar in his urine, *he is in good health,* although Fehling's solution is still reduced by his urine to a degree indicative of 1.2 per cent. of sugar."[36] With the blood loaded with sugar for eight years, and the patient maintaining apparent good health, it certainly does not indicate that the sugar is capable of doing much harm. Dr. W. H. White says: "Three months ago I saw a man, aged 62 years, whose urine had a specific gravity of 1.036; it contained much sugar, gave no ferric chloride reaction, and he appeared perfectly well. He said that sugar was detected in 1885."[37]. From 1885 to January, 1903, makes 17 years. To excrete sugar for 17 years and remain all this time in apparent good health, particularly at his time of life, does not indicate that sugar is a very bad thing to have, even an excess of, in the circulation. This clinical evidence is further confirmed by animal experiments. Exceedingly large quantities, as compared with the amount in normal blood, have been subcutaneously injected into dogs, without the slightest signs of toxicity. The experiments demonstrated that the animal body has great power in utilizing dextrose when administered in this way.[38] The fear of sugar, as sugar, is probably a vestige of the time when no one was allowed to sell it but the dealer in poisons, and he dared not dispose of it without a physician's prescription. The ghosts of such antiquated notions still continue to interfere with logical thinking even among many who think themselves entirely emancipated from them. If more evidence is still demanded in proof of the harmlessness of sugar the geographical and social distribution of diabetes ought to be sufficient. Find a place where sugar-cane is grown, and sugar consumed in abundance, and one is found in which diabetes is exceedingly rare or else is unknown. Find a region where carbohydrate food constitutes the bulk of that consumed and that place will be found to contain little diabetes. Discover a race that subsists exclusively on carbohydrate food and we discover one that knows no diabetes. Find a religion whose votaries must subsist exclusively on a vegetable diet and one will be found that knows little or nothing about diabetes. Now, on the other hand, the discovery of a class, people, or faith, where meats are largely consumed is quite likely to be one in which the death rate from diabetes is at its maximum. Such at least has, so far, been the results reported by those who have made a study of its geography. If we turn to Europe and America what do we discover? The very men and women whose daily food comes most nearly up to the standard of diet prescribed for diabetics are the very men and women in whom the cases of diabetes are most numerous and most fatal. They are the people whose daily ration is filled with fish, flesh and fowl, and in which but little room is left for bread or potatoes. The plain people who subsist on the more economical diet—a diet chiefly carbohydrate—know but little of diabetes. It is those who regale on table d'hote dinners who are the sufferers. They fill up on chicken and turkey, quail and partridge, venison and mutton, beef and oysters, fish and lobster, with only a minimum of carbohydrates. With an increase in the wealth of a nation comes an increase in the number of cases of diabetes, and *pari passu* with this, an increase in the consumption of proteid with a corresponding decrease in the consumption of carbohydrates. That others have observed this the reader has only to look up the literature on the subject to find the proof. In the United States the sugar-growing region is the one with the smallest proportion of cases.[39] Saundby tells us that "in Mauritius and British Guiana—countries in which the people are chiefly employed in the manufacture of sugar, in Africa where the sugar cane and other sweet fruits and vegetables form a large part of the diet of the natives, and in Ireland where the food of the peasantry is mainly vegetable, the disease is relatively rare."[40] Clemow tells us that, "The Jains, whose only animal food is milk and butter, escape it, and so also do the Sadhus, Yogees, and Chorboys of Muttra, who live almost entirely on sweets."[41] The same author adds: "In many countries outside India the natives live practically on nothing but farinaceous food, and yet do not develop diabetes; and in India itself the Jains, who live under similar conditions, escape it, and so also do Hindoo widows, who never touch animal food." The same author further adds: "It is, perhaps, a disease of civilization. Luxury, a sedentary life, a neurotic temperament, and town life all seem to favor the production of diabetes in the individual, and these are found in their highest development in the most civilized countries."[42] Edwards tells us that "Wealth and culture increase tenfold the predisposition to diabetes." Neither of these authors mention the fact that in all instances great proteid consumption and diabetes stick about as closely to each other as a shadow does to its substance. The Hindoo rich, coming from a people accustomed for ages to an almost exclusive diet of carbohydrates, show a lack of resistance that might be expected. The Hebrew, under oppression, forced by economy to subsist on carbohydrates and coming from an Asiatic carbohydrate stock, is likewise very susceptible. When rich he seeks to imitate his fathers, when leaving Egypt, by crying out for the "flesh-pots." This lack of immunity on the part of the non-exposed, suggests a possible infection, and, in another article, I will endeavor to show some facts bearing in this direction, while, at the same time, Cohnheim's enzyme activator, and the Islands of Langerhans, will be discussed, as to their relationship to the views here expressed.

CEREBELLAR HEMORRHAGE: REMARKS ON THE FUNCTIONS OF THE CEREBELLUM.

By JOSEPH COLLINS, M.D.,

NEW YORK.

Hemorrhage into the substance of the cerebellum is very uncommon compared with cerebral hemorrhage, and victims of it rarely survive. The subject of the following remarks seems, however, to have had such a lesion and now displays characteristic features of disease of that remarkable organ, remarkable because, though destruction of it in animals produces most striking symptoms, these symptoms disappear after a brief time, compensation being afforded by the cerebrum, particularly by the sensorimotor cortex. In reality we know very little of the indispensable functions of the cerebellum. Its chief rôle apparently is to regulate coordinated movements, but it has other and very important functions, as may readily be inferred from the symptoms that result when it is experimentally destroyed in animals or when it is diseased in man. The middle lobe, the worm or vermiform process, is functionally more important than the lateral hemispheres, and removal of half of this middle lobe in animals causes similar disturbance to that produced by removal of a lateral lobe. The effects of unilateral ablation are manifest in disturbance of equilibrium, peculiar attitude, disordered sensibility, and ocular symptoms. In human beings injury and disease of the cerebellum cause similar symptoms, and also disorder of speech.

The disturbance of equilibration which experimental destruction of the vermis or a hemisphere causes, is manifest by a tendency of the animal to rotate on its own axis. When the right half of the cerebellum is removed the rotation is toward the right, and *vice versa*. This phenomenon is not always present by any means, but unsteadiness of station and profound incoordination of all voluntary movement always exist, and this incoordination is much less when the individual is lying. No true paralysis occurs in cerebellar lesions, but despite this, in animals experimented upon, there seems to be a motor paresis in the limbs on the side on which the operation has been performed, and Bruce has suggested that these motor disturbances may possibly find explanation in the disturbance of the opposite cerebral cortex which results from the unilateral ablation of the cerebellum. It is possible, however, that impulses from the cerebellum to the muscles of the limbs go by way of a pathway from the cerebellum through Deiter's nucleus to the spinal cord, and

Fig. 1.—Illustrating position and attitude of the patient while sitting

to the cutting off of such influences is to be attributed this paresis which has been so often noted.

The attitude which the animal assumes after ablation of one-half of the cerebellum is characteristic. The neck is curved, the convexity towards the side of the lesion, and the head is twisted so that the side of the face corresponding to the side of the lesion is directed upward. There is a spasm in the muscles of the limb on the side of the lesion, and the knee-jerk is increased on the same side, diminished on the other, but this diminution soon disappears and both knee-jerks often remain exaggerated for a considerable time. Bruce believes that he has been able to make out a diminution of cutaneous sensibility in animals whose cerebellar hemispheres have been injured, is most marked in the limbs on the side of the lesion. This has not yet been noted

in man with cerebellar disease. Displacement of the eyes always occurs from unilateral ablation, both eyes being turned away from the seat of injury, the eye on the opposite side of the lesion usually being more displaced than the one on the same side, and nystagmus is invariably present.

The results of experimental lesion and destruction of portions of the cerebellum, such as one lateral lobe including the flocculus or half of the middle lobe, are very soon compensated, and after a few months animals that have been operated upon present no abnormalities unless very careful examination is made. If the Rolandic area of the brain, however, is destroyed, simultaneous compensation does not result, the cerebellar symptoms continuing. In the human being injury to

Fig. 2.—Showing position and attitude of patient while standing.

the cerebellum early in life and arrested development of the cerebellum may not give rise to any symptoms in adult life, the functions of the cerebellum having been assumed by other portions of the brain.

The functions of the cerebellum are so well indicated by the symptoms displayed even now by the patient whose history I am about to relate that his story seems to me worthy of record. He is a survivor of that comparatively rare condition, hemorrhage into the cerebellum. The majority of patients who suffer this accident soon succumb, especially if the lesion is of sufficient size to destroy a considerable part of the middle or lateral lobe, for then the blood may penetrate by way of the middle peduncle into the pons, and then, reaching the surface, becomes subarachnoid; it spreads out in the tentorium, or it may burst into the fourth ventricle.

The symptoms ending cerebellar hemorrhage may develop suddenly, or they may be preceded by such premonitory manifestations as headache, dizziness and retraction of the head. Pain is almost invariably at the back of the head and neck. In a few instances premonitory symptoms, such as vomiting and rotation, have been described. In the case of my patient the symptoms were so abrupt in their onset, so complete in their early manifestations, and so persistent in their course that the diagnosis was made early.

The patient is a tailor, 48 years old, who, until attacked with the illness that still incapacitates him, was in good health. In youth he had had several attacks of gonorrhea, but he denies syphilis. He had been accustomed to use tobacco and alcohol, sometimes rather immoderately. There is nothing in his history that may be construed to have any bearing upon his present trouble, nor had he any premonitory symptoms of the disease, which attacked him in August, 1904. While walking he was seized with violent ringing in the ears and dizziness, and he fell to the floor, but did not at once become unconscious. The man to whom he had been talking says that he noticed a twitching of the patient's face. He was taken home in a semi-conscious state and soon began to vomit. This continued for upward of four hours. I have not seen the physician who treated him at this time, but from the family I learn that he was semiconscious, restless, incoherent, and that he had fever. At the end of the third day he was taken to a hospital, and for three weeks he remained in a semi-conscious state, at the end of which time he gradually emerged from it, developing delusions that people wanted to kill him, etc. While in bed he is said to have been very "restless." That is, it was difficult to keep him still, and when he moved about it was with so much abandon that he would fall out of bed, and therefore had to be restrained. His speech was unintelligible, and this may explain his reputed incoherency, but his mind may well have been disturbed. He complained of double vision and of a dull pain in the back of the head, which compelled him to keep his head forcibly extended upon the neck. There was no incontinence of the sphincters. Examination of the urine soon after he went to the hospital revealed the presence of sugar. This disappeared in about three weeks.

At the end of three months he began to move about, and then very striking staggering was noticed. He is said to have reeled and tumbled like a drunken man. He himself said that he felt dizzy and deeply conscious of the sense of disequilibrium. Soon after he regained consciousness it was also noticed that he laughed and cried in an uncontrolable way and frequently.

His complaints, on entering the Montefiore Home, of which he is an inmate, were difficulty in walking, impaired vision, a peculiar heavy sensation in the back of the head and forced position of the head, vertigo, and dribbling of saliva. Examination then showed a well-nourished individual who sat with his head drawn backward and toward the left, the face tilted toward the right. This is the position which the head has constantly assumed since the disappearance of the acute symptoms. When he attempts to relate his symptoms he displays a very peculiar voice and speech.

The voice, which is high-pitched, has lost its timbre and the articulation is explosive and staccato. While talking he has attacks of uncontrollable laughter and the saliva dribbles. When he arises his movements are irregular, and on standing with the feet together and the eyes closed he sways very considerably. On walking his gait is typically "cerebellar," he sways and reels, pitches and tumbles, but rarely falls. He walks as well with his eyes closed as with them open.

Examination of his eyes shows marked nystagmus in all directions and pronounced arcus senilis. The pupils are equal and react to light, distance, and cutaneous irritations. There is paresis of the interni and externi of the left eye, *i.e.* of the third, fourth, and sixth nerves. The optic discs are pale. The functions of the fifth nerve are undisturbed. Facial innervation is more active and pronounced on the right side than on the left, and the pharyngeal reflex is brisker on the right side than on the left. The function of the eighth nerve on the right side is normal; on the left hearing is somewhat diminished. The ninth, tenth, eleventh, and twelfth nerves are normal. The jaw-jerk is present, but not exaggerated.

There is no conspicuous diminution of strength in the extremities. There is distinct hypotonia of the lower extremity. The knee-jerks are lively, the right one a little more so than the left. There is diminished Achilles jerk on the left side. The cremasteric and planteric reflexes are normal. The triceps and wrist reflexes are equal, not exaggerated. There is tremor of both hands, more of the right than the left, and it is of the type known as intentional, *i.e.* it occurs on purposeful effort.

There is no disorder of touch, pain, temperature or stereognostic sensibility. Deep muscular sensibility is preserved throughout. There is no atrophy or deformity. There is pronounced inability for the patient to pronate and supinate rapidly either hand, more difficulty in the right than in the left (Babinski phenomenon).

When the patient lies down the ataxia in both upper and lower extremities is very much less than when he is standing and attempting to walk. Repeated examination of the urine always reveals a trace of sugar. The highest percentage he has had is 0.25, and, aside from an excessive amount of indican, there are no other abnormalities save a high specific gravity.

The signs which he presents to-day are not materially unlike those which he had when he came to the hospital and which have just been related. He is a fairly well nourished man who holds his head in a peculiar position, the chin tilted upward toward the right, the head drawn backward toward the left. Such position of the head, first described by Hughlings Jackson (*British Medical Journal*, November 4, 1871), and now universally known as "cerebellar attitude," is very suggestive of cerebellar lesion, and it has often been pointed out that the direction of the face in such cases is away from the half of the cerebellum that is the seat of the lesion. As he moves his eyeballs into extreme positions distinct nystagmus may be noticed. When the right eye is covered and the left eye moved into forced positions toward the left and right, it is noted that these movements are incomplete, indicating the former paresis of the third, fourth, and sixth nerves, the two latter especially. When he attempts to narrate the events of his illness a striking alteration of the voice is evident. The voice has lost its tone color, there is no coordination of pitch and force. He opens his mouth for the words to come forth, and there is an explosion, then the next word is uttered in a whisper or nearly so, that is to say, he has apparently lost the capacity to articulate and to phonate regularly and harmoniously in very much the same way that he has lost the capacity to cause certain voluntary muscular contractions and regularly to inhibit them, to maintain equilibrium, station, and gait. In other words, the speech disturbance which he has is of a nature not unlike that which is at the basis of his ataxia. In addition to the abnormalities of speech that I have just referred to, there is a plaintive, whining note which so many patients with cerebellar and ponto-cerebellar disease have, and which is probably the result of incapacity, voluntarily and quickly to inhibit impulses going from the speech area in the brain to the peripheral speech apparatus. Aside from these factors there is nothing noteworthy about the patient's facies save some drooling of saliva, especially when his attention is distracted.

When he attempts to pick up coins a tremor develops, which increases with the purposeful effort, and which is therefore spoken of as an intentional tremor. This is to be seen more conspicuously when he carries a glass to his mouth, or when he attempts to put the tip of the index finger on the end of his nose. The movements have a certain abruptness which is unlike the rhythm of many coarse tremors. This tremor does not seem to be increased by closing the eyes, and it is to be seen in his handwriting as distinctly as anywhere else.

When the patient walks about, the most striking feature of his infirmity becomes evident. He starts as though he were going very well, but he has not taken two steps before he inclines abruptly to one side, pitches, reels, and seems about to fall, when he gathers himself and stops for a moment to get steadiness and confidence, and then goes on again. When he stands, his pose seems secure enough, but the upper part of the body, and particularly the head, manifest oscillations which give the impression that the individual is struggling to keep his equilibrium, but he maintains that he is not, and his statement is much substantiated by the fact that when his feet are put in approximation this titubation is not increased.

When the strength of his muscles is tested it is found to be retained to an astonishing degree. The muscles of his upper extremities contract energetically and powerfully, and when he lies down and is made to flex and extend the thigh and leg under resistance, he does it with power that would be attributed to a normal individual. While he is thus lying down he displays a condition that has been studied by Babinski, and out of which study has grown a sign of much importance in the diagnosis of cerebellar diseases. When he lifts his lower extremities from the table and holds them in mid air they are motionless. Now, in the healthy individual who attempts to do this there is, after a few moments, a flickering in certain muscles of the thigh, and soon afterward quite irregular movements of the legs. Babinski has endeavored to show that volitional equilibrium must be considered in two aspects: First, static equilibrium, *i.e.* equilibrium of the body in a state of repose, and kinesthetic equilibrium, *i.e.* equilibrium of the body in a state of movement, and that a lesion of the cerebellum may apparently produce the paradoxical result of very ma-

terially diminishing kinesthetic equilibrium (*i.e.* producing the disorder of gait which is illustrated in this man), while at the same time accentuating or increasing static equilibrium (*i.e.* producing the remarkable capacity for fixation of the lower extremities such as this man has when he is lying on his back). Babinski has further demonstrated that persons with cerebellar disease have incapacity to make successive movements rapidly, such as pronation and supination of the wrist. The rapid succession of such movements, or of any movements for that matter, involves the faculty of arresting suddenly a motor impulse, *i.e.* a contraction in a muscle or group of muscles, as well as sending to other muscles a new impulse which will cause them to contract. This faculty is essential to kinesthetic equilibrium, and for some reason not yet explicable it is disordered in cerebellar disease. The best way to distinguish this capacity is to have the patient lay his hand flat upon the table and then rapidly to supinate and pronate the hand. Patients with cerebellar disease do it very slowly or not at all. This patient, for instance, does it about one-third as rapidly as the average individual. Ten years ago Babinski demonstrated an alteration of the plantar reflex, which was constant in all diseases of the central nervous system, that caused a degeneration of the crossed pyramidal tracts of the spinal cord, and which has been accepted as one of the most important signs of organic disease of the nervous system. This sign of cerebellar disease, to which he has given the name of diadococinesia (formed from two Greek words, meaning successive and movement), is no less valuable as one indicating disease of the cerebellum.

Sensibility for touch, pain, temperature, and stereognosis seems to be well preserved. There is distinct hypotonia of the left lower extremity and there is also slight hypotonia of the right. The tendon jerks, knee and ankle, are not particularly abnormal. They are all lively, but it would be unjust to maintain that they were pathologic, nor, indeed, are the superficial or deep reflexes throughout the body in any way disturbed. The only one of the special senses that is disordered is that of sight, and this diminution of vision is dependent upon changes in the optic discs, which are in a state of partial atrophy.

In conclusion, then, the disease of the cerebellum which this patient has, or, perhaps, one might better say the alterations in the cerebellum sequential to an accidental occurrence, viz., hemorrhage of the cerebellum, illustrates fairly well the functions of the cerebellum as they have been determined by experimentation. The position of his head, the alteration of speech, the profound disturbance of gait, the nystagmus, the intentional tremor, and the inability rapidly to perform successive movements, form a complex of symptoms whose significance is unmistakable. They are pathognomonic of disease of the cerebellum, not of the disease which this patient has. As a matter of fact, when patches of sclerotic tissue develop in the cerebellum, in the disease that is commonly called disseminated insular sclerosis, the symptoms may be quite similar to those which this patient has, and there are cases of cerebellar tumor in which the symptoms of intracranial pressure, such as headache and vomiting, are not conspicuous, which have parallel symptoms to those displayed by this patient. Indeed, if we were ignorant of the history of this patient, and particularly of the details of his attack two and a half years ago, we should not be justified in making the diagnosis that has been made. Under such circumstances, knowing as we do that the symptoms of disseminated insular sclerosis often come on abruptly, indeed so abruptly as to suggest an acute inflammatory process, such as acute myelitis or encephalitis, it would have been incumbent upon us to consider very closely the possibilities of that disease. In doing so, one fact, however, would have had great weight in excluding it, and that is that disseminated insular sclerosis rarely, if ever, occurs after the fortieth year of age. Although the disease sometimes apparently manifests itself in a recognizable way as late in life as this, invariably it will be found that symptoms bespeaking its existence have occurred many years before. The patient has apparently only a moderate degree of generalized arterial sclerosis, and no evidence of renal or cardiac disease. What predisposed his cerebral blood-vessels to brittleness and what caused one or more of them to rupture we can conjecture, but we cannot state.

REPORT OF NINE CASES OF FRACTURE OF THE CARPAL SCAPHOID.

By LEONARD W. ELY, M.D.,

NEW YORK.

The following cases of fracture of the scaphoid, seen at the Roosevelt Hospital Dispensary, seem worthy of record at this time, while the treatment of this injury is still a matter of debate.

Case I.—C. B., aged 44, laborer, May 29, 1905. Fracture of the left carpal scaphoid; fracture of the olecranon. Five days ago the patient fell off a wagon on the flexed left hand; since then he has had pain in his wrist and has been disabled. The wrist has not been treated.

Examination: Crepitus. Sensitiveness over back of radial side of wrist in region of scaphoid.

Treatment: Plaster of Paris, slit up at sides, reaching to the end of the first phalanges.

May 31. Doing well. *X*-ray. Strapping for olecranon.

No further note appears on the history, and the patient cannot be found.

Case II.—C. M., aged 57, stationary engiuer, October 13, 1906. Old fracture of right carpal scaphoid; dislocation of right semilunar. Patient caught his hand in engine on August 16. He gives a distinct history of forced flexion of his hand upon a stationary forearm. The injury was followed by pain and swelling, and was treated on a diagnosis of sprained wrist. The patient worked for five weeks afterwards, and then was compelled to stop because the wrist became stiff.

Examination: The hand is swollen and in slight adduction. The wrist is thickened, especially on its radial side. Tenderness to pressure is present on the radial side of the wrist. Motion at the wrist is markedly limited and painful, and motions of the fingers are restricted. All the fingers seem equally involved. The *x*-ray shows fracture of the scaphoid and dislocation of the semilunar.

Treatment: Operation advised and refused.

Case III.—F. S., aged 27, boatman, October 20, 1906. Fracture of the left carpal scaphoid. Two days ago the patient fell on his superextended hand and injured his left wrist. Pain and swelling have been present since.

Examination: Hand swollen and edematous. Tenderness is marked over the wrist. Motion in the

wrist is painful. The hand is in radial abduction. Patient has secondary syphilis. The *x*-ray shows fracture of the scaphoid and probably dislocation of the semilunar. There is an old bullet in the radius, a relic of the Spanish war.

Treatment: October 22, ether. Plaster-of-Paris slit up side, reaching to phalanges, pinched in front and back over the scaphoid to prevent displacement. Hand put up in slight ulnar adduction. Crepitus over scaphoid could be felt under ether.

November 10, plaster removed. Extension free in fingers, flexion somewhat limited, especially of middle finger. Flexion limited in wrist. Treatment, strapping.

November 14. Some limitation in all directions

February 27, 1907. Practically perfect motion. No deformity. Patient is at work and says his wrist is as good as ever.

Case IV.—J. H., aged 20, driver, February 7, 1907. Fracture of left carpal scaphoid; sprain of right wrist. Patient fell off truck yesterday and injured both his wrists.

Fig. 1.—Case IV, right side.

Examination: Right wrist slightly swollen. No sensitiveness present, nor pain on motion. Left wrist swollen. Pain on motion, and limitation in all directions. Marked sensitiveness anteriorly and posteriorly over scaphoid. No bony deformity. Motion of fingers unrestricted. The *x*-ray shows fracture of the left scaphoid. No displacement.

Treatment: Plaster-of-Paris, slit up radial side, with dimples back and front over scaphoid.

No further note appears in the history, and the patient cannot be traced.

Case V.—C. G., aged 15, schoolboy, July 30, 1907. Fracture of right carpal scaphoid. Two weeks ago the patient fell on the right superextended hand. The injury was followed by swelling and pain in the wrist, and was treated with a diagnosis of sprain. Now the patient suffers pain when he uses his hand.

Examination: Slight swelling over the back of the wrist, just below the radius. Sensitiveness is present, most marked over the back of the scaphoid and in the snuffbox; not present in the palm. Crepitus. Practically no limitation of motion. No thickening. No displacement. The *x*-ray shows fracture of scaphoid.

Treatment: Plaster-of-Paris.

August 14. Plaster removed. No deformity. Slight resistance to adduction of wrist; other motions free. Motions in fingers unrestricted. Treatment, strapping.

August 23. Strapping removed. Massage ordered.

August 30. Steady improvement.

Fig. 2.—Case IV, left side.

September 6. Motion at the wrist still somewhat limited.

September 28. Flexion and extension slightly limited and cause pain when carried to extremes. Abduction also slightly limited.

February 14, 1908. District nurse reports perfect function.

Fig. 3.—Case V, right side.

Case VI.—G. M., aged 18, driver, October 16, 1907. Fracture of the left carpal scaphoid. Last night the patient fell, presumably on the superextended hand, and hurt his left wrist. Since then he has suffered pain.

Examination: Sensitiveness over the scaphoid, anteriorly and posteriorly. Swelling. Fingers free. All motions of wrist painful at extremes. The *x*-ray shows crack in scaphoid.

Treatment: Plaster-of-Paris, slit up.

February 1, 1908. Visiting nurse reports that patient had plaster on for three or four weeks, and then had it taken off at Harlem Hospital. Since then he has had no trouble whatever, and is at work.

Case VII.—P. F., aged 48, dockman, December 20, 1907. Fracture of the right carpal scaphoid. Patient fell off a ladder yesterday and struck on his right hand in the extended position. Pain and disability have been present ever since.

Examination: Tenderness over the scaphoid. Flexion and extension painful and limited. The *x*-ray shows fracture.

Treatment: Strapping.

January 31, 1908. Wrist is not swollen or deformed, but it is still somewhat painful. Patient has worked ever since injury.

Case VIII.—M. G., aged 18, August 31, 1907. Fracture of the left carpal scaphoid. Patient fell on the superflexed hand two days ago, and injured his left wrist.

Examination: Swelling and sensitiveness present over the scaphoid. All motions of the wrist painful. Fingers free. An *x*-ray picture was presumably taken, but no further record appears on the history, and the patient cannot be traced.

Fig. 4.—Case V, left side.

Case IX.—W. G. B., aged 54, driver, September 24, 1907. Fracture of the left carpal scaphoid. Five days ago the patient fell off a wagon and injured his left wrist. The hand was presumably in superextension. Treated for sprain.

Examination: Ecchymosis on front of the left wrist. Tenderness about the scaphoid. Motions in the wrist painful at extremes, but not much limited. No note appears as to what the *x*-ray revealed.

February, 1908. The wrist was put up in plaster-of-Paris. The patient did not return, but his wife says that he removed the dressing himself after a few days. Since then he has had pain in his wrist and has suffered some disability.

From these cases and from many others seen elsewhere, the following conclusions are arbitrarily drawn.

1. Fracture of the scaphoid is comparatively frequent, and is often mistaken for sprain of the wrist.
2. It often escapes detection and recovers without any treatment.
3. It is usually caused by a fall on the extended hand. It may be caused by punching with the clenched fist, or rarely by superflexion of the hand.
4. The one important symptom is tenderness over the scaphoid on the dorsum of the wrist in the "tabatière," or slightly internal to this spot. All the other classic symptoms of a fracture may be absent, except pain on motion.
5. If the fracture be accompanied by a dislocation of the semilunar, extension of the fingers, especially of the middle finger, will be limited and painful, and the disabiilty will be much greater.
6. The prognosis of simple uncomplicated fracture of the scaphoid is good; that of fracture with dislocation is less favorable.
7. A good treatment of simple fracture is immediate immobilization.
8. If the semilunar is dislocated, a piece of the scaphoid often goes with it.
9. If a dislocation is present, the dislocated bone must be replaced. If this is not possible, then it should be removed.
10. Roughly speaking, sensitiveness over the scaphoid, with a history of a fall on the extended hand, without much disability or swelling means simple fracture. If great swelling and disability are present, and the middle finger is held in rigid flexion, a dislocation accompanies the fracture.

167 West Seventy-first Street.

THE PULSE OF THE NERVOUS SYSTEM.

By J. HENRY DOWD, M.D.,
BUFFALO, N. Y.
GENITO-URINARY SURGEON, MERCY HOSPITAL.

Since the time Harvey discovered the circulation of the blood, the radial or other arteries have been the key to the circulatory system. The phosphates in the urine, although not discovered by so distinguished a man, and though their importance as an aid to diagnosis is but briefly referred to in text books, to the writer's mind, deserve the above title, "The Pulse of the Nervous System."

In considering the subject it must be understood that phosphates appearing in freshly passed urine, or phosphatic crystals found in the same, are not referred to; also that the earthy phosphates, although of importance, are in such small quantities that their presence will be but briefly noted. On the other hand the phosphates under consideration are known as the alkaline phosphates and are only precipitated by an alkaline solution.

The average quantity of phosphoric acid secreted by the kidneys in a normal state is 3.8 gms., which varies greatly in ordinary healthy individuals. They may be very low, and on the other hand they may be doubled or even quadrupled in the urine and yet no pathological condition be present. Phosphoric acid occurs in the urine in combination with the alkaline earths—earthy phosphates in the form of calcium and magnesium, insoluble in water, but soluble in acids.

The alkaline phosphates occur as acid sodium phosphate and potassium phosphate, soluble in water and in alkaline fluids. Turbidity of freshly passed urine due to phosphates, and the same occurring on boiling is always due to earthly phosphates, and when seen with the microscope the precipitate looks like microscopical sawdust, if such a term may be used. They never appear as crystals unless the acid magnesium phosphate is acted upon by ammonium when ammonio-magnesium phosphate crystals form, fern-leaf in shape, or after long standing the coffin-lid shape may also appear.

The phosphates in the system are derived from

the food, and their appearance in the urine is influenced greatly by the various articles of diet and also by certain drugs. Thus, there is a marked increase of phosphates on an animal diet, and such drugs as phosphorus, strychnine, and lecithin (which should be considered a food) increase them greatly, provided assimilation is perfect.

The amount of phosphates depends greatly upon the decomposition of nuclein and lecithin. Foster's Dictionary says "Lecithin is a class of bodies found in the brain, nerves, amniotic fluid, yolk of eggs, bile, spermatozoa, and certain vegetable substances."

Nuclein is a complex body found in the yolk of eggs and is present in all cell nuclei. More recent studies show that lecithin should be considered a food rather than a drug. It is a highly complex fat containing a nitrogenous substance in which phosphorus is present in organic combination. It is a constituent of every cell, its universality showing its indispensability to life. This being true it must at once appear that both are derivatives of one of the most important structures of the body, viz., the nervo-vital cells. Therefore there can be no argument other than that irritation of the nervous system will increase the output of lecithin and nuclein in the form of phosphates in the urine, providing these substances are there to be decomposed.

On the other hand, where there is no surplus of nuclein and lecithin, no matter how great the irritation, phosphates are always diminished. Textbooks tell us that elimination of phosphates is influenced by the food, by the time of day, and by certain diseases. To a great extent this is true, but when it is recalled what an important part the nervous system plays in all diseased conditions is it not fair to assume that the rise and fall in the phosphates are not due to any disease *per se*, but to influences exerted on the nervous system?

Furthermore we are all aware what position the nervous system takes in disease, how the calm and robust withstand disease, infections, etc., and rapidly recover, whereas it is exactly the reverse in the delicate and especially in the markedly neurotic.

In fact, in the writer's opinion the state of the nervous system as indicated by the phosphates in the urine is the keynote to all diagnosis, prognosis, and treatment. Facts must not be lost sight of that the nervous system controls every organ, every function, every tissue in the human economy. With such truths staring one in the face is it not true that impoverished vital cells, robbed of their force, can delay resolution, or on the other hand a perfectly normal cell impart tone to every tissue? But a step further: is it not as uncomfortable to be too warm as too cold? Suppose assimilation to be practically normal and each cell getting its proper amount of nuclein and lecithin, yet the urine shows that more phosphates are being eliminated than should be.

Certainly one thing is evident; a reserve force is being drawn upon. This increased decomposition shows but one thing, an abnormal destruction, and it will be found to be accompanied by the exaggeration of every symptom of the existing disease. All physicians know what nervous excitability means in the treatment of disease, and the continual overdraw means depletion of nerve force. A nerve cell deprived of its normal reserve force will manifest itself in the production of general systemic depression sooner or later, and such a condition we usually find following trivial complaints. Leaving aside true or organic conditions, let us consider what may be termed false or functional, or those where there is no pathological change, but which if allowed to run may lead to organic changes.

A functional condition is one where there is a deviation from the normal state, the cause of which is both direct and indirect, yet no pathological condition may exist.

The "direct" cause is removable by drugs, advice, etc., and the "indirect" is the nervous influence easily and quickly discoverable, the removal of which may postpone the development of a pathological condition. We are aware that the control of the blood-vessels is entirely through the vasomotor nervous system.

We know that inflammation is due to bacterial infection, that bacteria to grow and flourish must have a proper soil, and this we find in long-continued congestion. But from another standpoint there appears another directly opposite state of affairs: if tone cannot be conveyed to the chronically congested or inflamed parts on account of a lack of nerve force, the condition must remain stationary.

That lecithin and nuclein exist in the cells, in reserve, is plainly shown when a person in a state of pronounced nervous excitement for days or weeks does not take food to speak of, yet the phosphates in the urine are greatly increased. Let this condition continue for some time and it will be found that the phosphates are decreased far below the normal. Although there may be no anemia or organic condition present, systemic prostration varies to a degree where that person may have to take to his bed. Proof that the phosphates are derivatives of the nervo-vital cells is shown when the cause is removed or sedatives given. Almost immediately the heavy withdrawal is checked as is shown by the urine. For clinical purposes only an average approximate estimation of the phosphates need be considered. Accuracy is impossible in any case, for each one must be considered a law unto himself." For a person in apparent health there may be a very small amount found in the urine, whereas, in another in the same condition of health, from the viewpoint of external evidences, there may be four times what may be considered normal. Certainly where the phosphates vary so greatly there must be some cause, this being found in the state of the nervous system and discoverable in a very few minutes by an examination of the urine.

In a great number of specially selected cases where there was perfect tranquillity and no pathological condition, and examination of the urine showed a practically normal specific gravity, reaction, amount, total solids, etc., the writer would suggest the following as a practically normal phosphatic elimination, the earthy salts being included: Using a test tube holding about 30 c.c., 20 c.c. of urine is placed therein and 8 c.c. of Tyson's alkaline solution added.

The mixture should change to a milky character at once, varying in degree of density according to the amount of phosphates present, also according to the condition of the surroundings; for instance, more quickly when warm than when cold. The test tube should be placed to one side for ten minutes. The phosphates will sink rapidly according to their specific gravity compared with that of the fluid. That is, if they be normal and well formed they sink rapidly, whereas, if small, light, and immature, they fall very slowly, even at times remaining almost stationary, giving a general turbidity throughout the whole fluid. But in the majority of cases, if normal, in about ten minutes they will sink to the bottom, occupying a space that can be filled by 3 c.c. of fluid. The size and weight are important factors to be considered. At times they fall to what may be considered a normal index, but in appear-

ance the sediment is fluffy, light in color, and easily movable upon agitation. When normal or in excess, they settle like fine sand, heavy, and agitation does not disturb them much. In the former condition they must be considered deficient, even though they reach the normal index.

Phosphates precipitated by Tyson's solution appear fern-shaped, but the crystals vary as to size. The usual normal size is about five-eighths of an inch in diameter, but according to the condition of the nervous system they may be only one-eighth of an inch relatively when viewed with ½-inch objective. The size of the crystals is quite important as to proof of the amount, also the condition present. In cases where they are greatly increased, as where nervous excitement is high and the condition is in its incipiency, they may appear very small on account of the rapidity with which they are formed. Also, when they are small in amount from long-continued drain on the residual nuclein and lecithin, and when being precipitated practically from the food, they are small. This can easily be proven by watching a case. Watch them grow from infancy to manhood. In other words, take a case as above, remove the exciting cause, feed the patient on food and drugs rich in phosphorus and lecithin. Weekly examinations will not only show an increase in size, but an improvement in the condition of the patient.

Clinical Importance of the Pulse of the Nervous System.—As the radial or other convenient artery tells the condition of the circulatory system, so the phosphates in the urine tell us the condition of the nervous system. They go further than the pulse, acting as a barometer, for they tell of the past and foretell the future. The coming storm may be prognosticated and combated before it breaks in all its fury. Although there may be no external evidences, a large increase in phosphates means nerve and especially central irritation. No matter how or when this condition develops, if it continues, sooner or later the reserve will be exhausted and we shall find a neurasthenic with all the ills from which such patients suffer.

In the same way, by the phosphatic index, pathological conditions may be assisted to a marked degree. No one will deny the pronounced influences that a highly nervous state exerts upon a sick individual, although there may be no external evidences of the irritation of the nervous system. In others, resolution is slow or becomes stationary. The phosphates in both cases tell what influences the nervous system is having on the condition, first, by great excess, and later by a diminished amount.

Medication in nervous cases should be carried on only as the phosphates indicate, after the physician has learned to regard each patient as a law unto himself. Cases of lassitude almost bordering on prostration may call for sedatives rather than stimulation. Pain may be the nerves crying for food, and in many of the indefinite conditions treated for rheumatism it will be found that the above is the true cause and that where salicylates, etc., had no effect, drugs and food rich in nuclein and lecithin will at once relieve. In cases in which from over-irritation the nerves are crying with pain, drugs of an opposite nature will at times give the desired result. In conditions especially where there is prolonged illness, an estimation of the phosphates should be made every few days, for when a marked withdrawal of the surplus is shown the checking of this will often to a very great extent obviate the prolonged convalescence.

Conclusions.—Much of the suffering of to-day is due to an imperfect adjustment of the mental balance wheel.

Taking the phosphatic index is as important as taking the pulse rate, if not more so, and far more important than other procedures to which much time is given.

Bedside examinations can be made in ten minutes, using preferably the urine secreted between eight and twelve o'clock in the morning.

In disease of the nervous system which cannot be accounted for, and in the case of indefinite pains, the phosphatic index should be the guide for medication.

When a positive cause has been removed and the phosphates do not rise under appropriate food and drugs, one should look to the assimilation; it may be faulty.

Pregnancy, the third week after conception, and up to the third month, is positively shown by the condition of the fern-shaped leaves. If present, a goodly number are found stripped of their feathers; otherwise they are almost perfect.

Remember that the nervous system controls the whole economy, in health or disease, and if the cells are unduly excited, or rendered almost useless by heavy withdrawal of their reserve, conditions may be aggravated or cease to improve as the case may be.

43 West Tupper Street.

SOME CONSIDERATIONS IN THE MANAGEMENT OF BURNS AND SCALDS IN INFANTS AND CHILDREN.

By MEDWIN LEALE, A.B., M.D.,

NEW YORK.

PHYSICIAN ROOSEVELT HOSPITAL, O.P.D., AND FORMERLY ATTENDING PHYSICIAN FLOATING HOSPITAL FOR CHILDREN OF ST. JOHN'S GUILD.

There are perhaps no cases more important, or which demand greater skill on the part of the attendant, than those of severe burns and scalds occurring in infants and young children. Many lives are menaced, nay even sacrificed, in addition to the numbers who grow up permanently deformed by a neglect of the minute details of management. These bad results, which are in many cases due to perfunctory treatment, are especially noticeable to one who has been engaged in extensive hospital and dispensary practice, where many cases finally drift to see if anything can be done to render less unsightly the ultimate deformities or disfiguring cicatrices. At this late date little or nothing can be done, the treatment must be preventive by proper management at the time of and immediately following the receipt of the injury.

Cheever of Harvard states that about three-fourths of all burns and scalds occur in children, and, when one considers the greater risk which they run, it would seem to be a fair proportion.

In considering this subject it is well to bear in mind, that the prognosis of burns and scalds in infants and young children is relatively much more severe than in adults. It is generally known that mere reddening of more than two-thirds of the body from this cause, or a burn or scald of the second or third degree involving one-third or more of the surface will usually produce death in the adult, while relatively less extensive burns or scalds in infants will at times lead to a fatal result. Infants and children are more apt to succumb to shock, and later, after reaction has set in, congestion of internal organs from vasomotor paresis may cause serious consequences.

Shock, according to Bryant, kills more than one-

half of the fatal cases. Infants, young children, and those in whom the senile degenerations are well marked, suffer more severely from this condition. Many deaths may be the direct result of fright, pain, or paralysis of the heart. Sonnenburg and others state that overstimulation of the superficial sensory nerves may produce death by reflex cardiac paralysis, and Crile in a recent lecture before the Harvey Society accentuated the great importance of this as a factor in the production of shock. From this we can readily see the necessity of doing everything in our power, both psychically and with an intelligent use of drugs and the physical means at our command, to allay fright and lessen these afferent sensory impulses. It is well to remember that shock may not fully develop in these cases until forty-eight hours after the receipt of the injury.

It is generally understood that the internal organs have an undue strain placed on them, owing to their being called on to do part of the work of the injured or destroyed skin. This is particularly so in regard to the kidneys, which often become extremely congested, the congestion leading, if prolonged, to serious consequences. An acute nephritis, or later even amyloid changes may result. In many cases we find an albuminuria, and at times a hematuria, and often where there is a high temperature both these conditions rapidly supervene. Ponfick first called attention to yellowish-brown casts in the urine and kidneys of these patients, which are caused by the presence of broken down red blood cells. The urine of those dying during suppuration contains certain abnormal end products from the body proteids; a series of bases of the pyridin type, cystin or a substance closely allied to it, and other proteid derivatives.

Several theories have been advanced to account for the stasis of the internal organs. Perhaps one which should be given much weight is that of Max Schultze, that the conversion of the red corpuscles into small globules after their destruction is the chief cause of this pathological condition. It is during the stage of reaction lasting from one to two weeks or longer, during which time there is usually an elevation of temperature, that internal congestions occur, which latter, if long continued, run on to inflammation or degeneration. In infants and young children also all the structures, the brain, lungs, heart, blood-vessels, etc., are more easily affected than in the adult. Convulsions are more common and may lead to death. In some cases at necropsy an engorgement of the vena cava and right heart has been found.

In children also the heat seems to have a more severe action on the blood corpuscles, the destructive changes being more marked. This is not strange when we consider the thinner skins of the corpuscles in early life. This destruction of the red blood cells has a very pronounced effect on respiration and metabolism, and, in addition to the great irritation of the nervous system, is a potent factor in the production of shock. This destructive change in the blood often leads to thrombus formation in the vessels.

The loss of body heat is a serious factor, and must be carefully guarded against by every means at our command. A sudden marked fall in temperature is serious, and later during the stage of reaction is of grave prognostic omen. Vomiting coming on shortly after the receipt of the injury is a bad sign.

Among the later and less frequent sources of danger are exhaustion from prolonged suppuration or other causes, erysipelas, pyemia, tetanus, or any intercurrent affection tending to lower the vitality which is already taxed to its utmost. In burns about the neck or throat edema of the glottis is not an infrequent complication. Perforation of the intestine as a result of a duodenal ulcer is not so frequent as generally supposed; although most textbooks seem to lay stress on this condition, it may be said on the strength of several series of autopsies by a number of careful observers, that this complication is very infrequent. Ulcers have been encountered elsewhere in the intestinal tract in a number of cases, but their direct connection with the injury is hard to prove.

Of all the regions of the body extensive burns or scalds of the abdominal or anterior thoracic regions present the most serious outlook. This is probably owing to their greater proximity to the vital organs, and the thinner parietal wall.

In giving a prognosis we must consider from what intense burns a child may recover. I have seen many remarkable recoveries; in many of the worst cases there in hope. To show what may be survived, I will refer to a case reported by W. W. Keen in the *Annals of Surgery*, May, 1907, in which an infant seven months old lay with its head on live coals in an open fireplace for a period of from twenty to thirty minutes, where the result was a necrosis of the entire osseous cap of the cranium. The ultimate result was epilepsy partially relieved by an operation for the relief of pressure from the contraction of tissues.

Before passing I would like to say a few words in regard to burns from electricity, which are becoming more and more frequent. Shortly after the injury the affected area becomes covered with a brownish eschar, and owing to some as yet fully undetermined pathological change these burns heal more slowly. The requisite strength of current to cause death in children is somewhere between five hundred and fifteen hundred volts. Death is the direct result of paralysis of respiration or of heart action. The constitutional symptoms are usually less marked in burns from this cause, and the pain is often not so severe. At the line of contact the skin is black, but the surrounding skin is dry and pale. The trophic disturbances are more marked; hence the reason for the more frequent and more extensive sloughing. The extent of these injuries is often misleading on first inspection owing to the fact that much damage may be done beneath the skin.

In lightning stroke, along the course taken we find various markings from burns of variable intensity, and these at times may assume fantastic shapes. There is more destruction of tissue at the points of entrance and exit. These markings are due to hyperemia and ecchymosis.

It is not the object of this article to enter into a full line of treatment that these injuries should receive, but merely to state a few of the essentials embodying some of the procedures which have furnished the author the best results. The one thing of paramount importance is to see that everything coming in contact with the wound is sterile; hands of the surgeon (gloved or otherwise), instruments, dressings, etc. The wound must be carefully freed from all foreign substance, dirt, clothing, discharge, blood, etc., vesications being carefully drained, as their content, serum plus fibrin ferment, on coagulating forms a good culture bed for the development of pathogenic bacteria. The formation of this fibrin ferment may determine an early rise of temperature before the period of sepsis if the latter should supervene. The wound must be care-

fully irrigated with an antiseptic solution and after using many different antiseptics I have found that of all aqua hydrogenii dioxidi is the most reliable. This seems to possess more of the requisite properties. It is a powerful oxidizant of organic matters, and an active coagulant of albumin. Pus is rapidly destroyed, the corpuscles being broken into detritus, and the solution comes into direct contact with the bacteria which it rapidly destroys. It is also slightly styptic, which renders it doubly serviceable where there is oozing from the surface. This antiseptic, however, is not suitable for prolonged application. I use a warm aqueous solution in a strength varying from 1 to 6 to 1 to 10, and after irrigating the wound thoroughly with this, I follow it up with an irrigation of warm normal saline solution or a 3 per cent. solution of boric acid. Boric acid solution alone I do not rely on, as it is inefficient as a germ destroyer, but it has considerable antiseptic power. Careful experiments of Sternberg (*American Journal of the Medical Sciences*, LXXXIV, 321), and E. Andrews (*Chicago Medical Examiner*, 1889, LVIII), have thrown much light on the effects of boric acid and its solutions on bacteria.

The next important factor in local treatment is protection of the wounded surface. Where the injury only involves the epidermis, the derma not being affected, after employing the antiseptic and irrigating solution, I often use a very thin ointment made fresh at the bedside with a pure sterile English oxide of zinc powder and pure olive oil rendered sterile by boiling, which can be made in any thickness desired, care being taken to have it perfectly smooth. To this may be added, if desired, 3 per cent. of boric acid. This spread in a thin even layer on folded gauze minimizes irritation, which, if pronounced, would injure the deeper layers of the skin. This dressing changed frequently in conjunction with the antiseptic irrigations is often all that is required in these superficial burns or scalds, and they heal rapidly. As a general rule burns and scalds involving the papillary layer do best when protected by means of rubber tissue or silver foil, placed in overlapping strips ½ to 1 inch wide, thus allowing the escape of discharge from the wound, and its being immediately taken up by the overlying layers of gauze, which latter in no part comes in contact with the wound surface.

The delicate structures of the newly forming skin or the developing granulation tissue easily suffer from the contact of dressings, and therefore the importance of using some nonadherent nonirritating material can be readily understood. During the process of repair the dead tissue is thrown off from the living by the formation of a dry slough; the ideal healing taking place when the slough is aseptic. Owing to the fact that, at the time of the injury bacteria are not only present on the surface where the antiseptic easily reaches them, but also often in the deeper layers of the skin, where it is difficult or impossible for the solutions to penetrate, the great difficulty and at times impossibility of maintaining an aseptic condition is apparent. We must keep in mind, that other things being equal, the more exuberant the granulations the denser the scar tissue resulting. Solutions of nitrate of silver applied to restricted areas and used with care and judgment are valuable here. Besides the deformities, contractions, etc, resulting from dense scar tissue, particularly if this tissue is poorly nourished, there may result at a subsequent period ulceration, or in rare cases even a keloid or epithelioma. Ulceration as a sequence is more apt to occur in children who are syphilitic or tuberculous.

I desire to accentuate the great importance of constitutional treatment in these cases. Great vigilance, foresight, and judgment are often required to bring the little patients through the periods of shock, reaction, and exhaustion, if the latter supervenes. They must be placed in a well-warmed though thoroughly ventilated room, carefully avoiding all draughts. Pain if at all severe, as it is in most cases, is to be controlled with some preparation of opium, and an intelligent use of this drug will be found greatly to lessen shock, and therefore will increase the chances of the patient. In infants and young children the preparation on which I mostly rely is the camphorated tincture, in doses of 1 to 15 minims, repeated at short intervals until quieted. In those cases, however, where it is difficult to get the patient to take anything by the mouth, or where the stomach is intolerant, I give minute doses of the sulphate of morphine, gr. 1-100 to gr. 1-20, repeated as required. The extremities should be kept warm, and all undue exposure of the body surface avoided. I have found that in many cases where shock is pronounced the continuous irrigation of the colon with a hot decinormal saline through a double flow rectal tube or large catheter is of great service, not only in raising the blood pressure, but in replacing the body heat lost from the denuded surface. Medicinal stimulants may be valuable, but their use during the early stages is secondary to the foregoing measures. When stimulants are given it is often best to administer them hypodermically.

During the stage of reaction we must carefully watch the emunctories, especially the kidneys, and any abnormal conditions should be promptly met by appropriate treatment. All irritability of the stomach should be carefully avoided. Vomiting coming on seems to be best met by combining a small dose of atropine with opium. We shall find that the patients do best by greatly restricting the amount of food during the first hours or days, the action of the stomach and intestines being carefully observed as we strengthen the formula or extend the dietary. Later, when the patient needs every supporting measure, and the stomach and intestines are tolerant, a liberal supporting diet is indicated. For making the patient more comfortable the Hebra water bed or one of its modifications is often of service.

A REPORT OF FIFTY CASES TESTED BY THE CALMETTE OPHTHALMO-REACTION TEST FOR TUBERCULOSIS.

By CHARLES GRAEF, M.D.,

NEW YORK.

OCULIST AND AURIST TO FORDHAM HOSPITAL; CLINICAL PROFESSOR OF OPHTHALMOLOGY, FORDHAM MEDICAL COLLEGE.

The test as recommended by the originator, Calmette of Lille, is made by instilling into the conjunctival sac of the patient one drop of a one per cent. solution of Koch's old tuberculin. In patients affected with tuberculosis in any part of the body a reaction occurs in from three hours to three days. This may be only a slight irritation of the palpebral conjunctiva, with congestion of the caruncle and some complaint by the patient of a feeling of sand or grit in the eye, or may develop into a pronounced conjunctivitis with swelling and redness of the entire conjunctiva, edema, and discharge, as is seen

in well-marked cases of "pink eye." The reaction is not, apparently, connected with the stage or extent of the disease present. The most marked reaction observed was in a case in which sputum examinations have remained negative and no signs of a positive kind are obtainable on repeated examination of the patient. The tuberculin was used experimentally and a marked reaction followed. This with a one per cent. strength,—the one-half per cent. first employed having shown no reaction. On the other hand in a case in the late stage of the disease—that of a young man of 22 years with advanced lesions in both lungs, in the larynx, and in the pharynx—no reaction was obtained with three different instillations. The first test was made with the one-half per cent. strength, and, no reaction following, two more tests were made with the product of two different laboratories. Absolutely no reaction occurred.

In making the tests a preliminary series of six cases was tried with a one-half per cent. solution instead of the one per cent. advised by Calmette. This gave the reaction in four cases but failed in the other two in one of which a subsequent use of the stronger solution gave a positive reaction. It would seem, therefore, that the solution as advised by Calmette is more likely to be satisfactory.

In none of the fifty cases examined were there any unpleasant symptoms. Proper precautions should, of course, be taken in the use of this agent and in seeing that eyes unsuitable for testing purposes are left alone. So far as the writer has observed no undue excitement has been reported as following its use in any eye with which such precaution was taken, and the reports made so far include several thousand cases. The drop is put into the lower conjunctival sac, the lower lid being drawn out for the purpose and held for a brief time afterwards to prevent the material being perhaps too rapidly passed down the tear ducts. The agent is supplied in tablet form which is easily prepared for use by dissolving one tablet in fifteen drops of boiled water. If only an occasional test is to be made the pipettes, each containing a drop of the solution ready for use, would seem preferable. Care should be taken to avoid the possibility of getting a spicule of glass from the freshly-broken end of the pipette into the conjunctival sac if this plan is followed. I found the pipette a more troublesome plan, but on the whole a more reliable test than the tablets. The solution is put into one eye only, leaving the fellow eye as a control by which the less marked changes in the eye under observation may to some extent be adjudged.

Conclusions. 1.—The test seems to be a fairly reliable one; well worthy of wide and repeated trial at least.

2.—In some advanced cases no reaction will occur—a matter of little moment if the test proves reliable in early cases, whatever the reason for this peculiarity may be.

3.—Some allowance should be made for possible faults in the tuberculin as furnished at present. From the observations made on these cases I should regard the ophthalmo-reaction as good evidence of the presence of tuberculosis. In one of the cases a diagnosis made in this way was afterward confirmed by finding the baccilli in the sputum.

My thanks are due to the staffs of Fordham and of Lincoln Hospitals for their kind courtesy in furnishing me opportunities to make these tests and for much help in observing and recording the results.

A synopsis of the cases is as follows:

1. C. S. Man æt. 29. Possibility of tuberculosis in chest. No positive signs obtainable. Sputum negative. No reaction with one-half per cent. strength. Positive reaction at the end of twenty-four hours with one per cent. Lasted four days.

2. L. M. Man æt. 22. Advanced disease in lungs, larynx, and pharynx. No reaction, although three separate tests were made at intervals of four days.

3. N. G. Man æt. 23. Acute pneumonia, recovering. Has an evening rise of temperature to 103°. Positive reaction in three hours. Tubercle bacilli found in sputum afterwards.

4. W. H. Man æt. 39. Recovering from acute lobar pneumonia, right side. No reaction.

5. D. N. Man æt. 39. Alcoholic case with possible tuberculosis. No positive signs. No reaction.

6. P. M. Man æt. 54. Sputum positive; physical signs positive on the left side; an early stage. Marked, positive reaction in three hours. Lasted three days.

7. R. H. Girl æt. 18. Acute lobar pneumonia, beginning. No reaction.

8. A. O'C. Woman æt. 60. Suspected tuberculosis. Râles over both lungs. Marked reaction in three hours.

9. P. McD. Woman æt. 39. Both lungs involved; late stage; sputum full of bacilli. Positive reaction in three hours with a one-half per cent. strength; later a more marked reaction with one per cent. solution.

10. M. M. Woman æt. 21. Late stage. Both lungs far gone. Similar results as in the preceding case.

11. L. B. Woman æt. 31. Acute secondary syphilis. No suspicion of tuberculosis. No reaction.

12. M. D. Woman æt. 42. Chronic articular rheumatism. Negative.

13. W. B. Woman æt. 20. Cured case of pneumonia, left side. Negative.

14. P. G. Man æt. 40. Positive signs in lungs. Sputum positive. Positive reaction, but not until thirty-six hours after instillation.

15. M. M. Woman æt. 21. Recovering from pneumonia and pleurisy, left side. No reaction.

Cases 16 to 20 were in children from ten to twenty years of age, of a father who has recently died from phthisis after a long illness, the children living in the same home. All proved negative to this test.

21. C. E. Girl æt. 21. Hypertrophic rhinitis; persistent cough; good physique. No reaction.

22. P. P. Man æt. 32. Sputum positive; physical signs positive; early case. Positive reaction in three hours.

23. J. O'M. Man æt. 35. Sputum negative; suspected tuberculosis. Reaction positive.

24. Mother of the children in cases 16 to 20. Negative.

25. G. R. Man æt. 25. Suspected tuberculosis. Positive reaction twenty hours after instillation.

26. R. H. Man æt. 24. Case of tuberculous peritonitis. Abdomen opened by surgeon. Positive reaction after eight hours.

27. J. V. Man æt. 22. Tuberculosis of the hip. Positive reaction in six hours.

28. D. H. Man æt. 22. Right apex diseased, and there is an ischiorectal abscess. Reaction positive.

29. A. C. Negress æt. 28. Both apices involved. Reaction absent.

30. L. H. Negress æt. 22. Suspected case of tuberculous peritonitis. No reaction.

31. C. H. Aet 28. Pott's disease, with sinuses. Reaction absent.

32. M. S. Aet. 20. Glands enlarged in neck. Reaction after twelve hours.

33. S. A. Woman æt. 27. No reaction.

34. H. R. Woman æt. 28. Lues; active, tertiary lesions. Negative.

35. N. B. Æt. 24. Pulmonary tuberculosis; early; sputum positive. Reaction positive in eighteen hours.

36. C. F. Girl æt. 17. No suspicion of tuberculosis. No reaction.

37. E. R. Negro æt. 37. No definite diagnosis; suspected spinal trouble. No reaction.

38. S. L. Woman æt. 29. Tuberculous laryngitis; sputum positive. Reaction positive after eighteen hours.

39. G. S. Woman æt. 80. Bronchitis. No reaction.

40. C. A. Æt. 49. Malignant disease. No reaction.

41. W. H. Man æt. 25. Undoubted case of tuberculosis of the lungs and larynx. Positive reaction in four hours.

42. P. P. Man æt. 41. Advanced case of pulmonary tuberculosis; sputum positive. Reaction marked in three hours, lasting three days.

43. B. P. Full blooded negro æt. 49. Sputum positive; clinical signs positive; advanced case of pulmonary disease. Reaction positive after twenty-four hours.

44. J. T. Man æt. 26. Paraplegia, psoriasis; sputum negative. Reaction positive, eighteen hours.

45. S. S. Woman æt. 81. Very stout woman; fatty heart. Reaction negative.

46. M. M. Girl æt. 22. Suspected pulmonary tuberculosis. Reaction negative.

47. J. H. Laryngeal ulceration; syphilitic history. Reaction negative.

48, 49 and 50. Healthy adults. No reaction.

1076 Boston Road.

SUCCESS AND FAILURE IN NAUHEIM CURES.

By PAUL C. FRANZE, M.D., L.S.A., Lond.,

BAD-NAUHEIM, GERMANY.

Although Nauheim owes its present popularity in no small measure to a generally increased prevalence of heart affections, there can be little doubt that its widespread reputation is essentially attributable to the intrinsic merits of its waters, and to the balneological methods which have been evolved by observation and experience.

The three springs which in Nauheim are available for bathing contain from 2.5 to 3.5 per cent., approximately, of the chlorides of sodium, lithium, and calcium, besides some iron, and a considerable amount of free carbonic acid gas. Moreover, the natural temperatures are just about suitable for bathing, without any or much alteration.

The physiological action of these springs is supposed to be as follows: The carbonic acid and the salts cause the capillaries of the skin to dilate and stimulate the cutaneous sensory nerves. These convey the stimulus to the nerve centers, thus stimulating by reflex the vagi and the vasomotor nerves. The result naturally is increase of vasomotor tone and regulation of the heart's action. Now if the bath be cooler than the body temperature there is initial contraction of the superficial capillaries with subsequent dilatation. This latter is called "reaction." The irritative action of the chemical ingredients of the water counteracts the capillary contraction and increases the subsequent dilatation. The contraction means a short increase of resistance, thereby stimulating the heart to a more powerful effort. Reaction on the other hand lessens resistance, and relieves the heart. Thus the mineral baths strengthen the heart and lessen its work at the same time, this latter by reducing resistance.

The therapeutic action which is the rule, is the following: The pulse generally is somewhat slowed, blood pressure as a rule rises in cases of originally low pressure, and falls in the reverse cases. Thus a somewhat curious, though very fortunate, action is manifested, viz., a regulating one. In a course of baths, therefore, in suitable cases, the result is reestablishment of compensation.

Exercises and massage, which are used, too, act similarly as they also reduce resistance and stimulate the heart, the former by the freer flow of blood in the contracting muscle, and the latter because the freer reflux of venous blood to the heart together with a stimulation of the sensory nerve terminations, which invariably accompanies that of the motor nerves, bring about more vigorous contractions of the ventricles.

Electric baths with the faradic and sinusoidal currents are of late also occasionally employed in Nauheim. Careful experiments and observation have convinced me that they have important physiological and therapeutic actions on the circulation, which are similar to those of the mineral baths, though not quite identical. Besides these, various other curative agents are occasionally employed in Nauheim, of which, however, only the mineral drinking springs call for special notice. Four of them are available, their principal ingredients being chloride of sodium and carbonic acid. They are supposed to have a beneficial influence on the intestinal and respiratory tracts.

All the agents mentioned have, besides the curative properties already dealt with, that of accelerating metabolism, a most important thing in circulatory disorders.

Success in Nauheim treatment depends less upon the kind of heart lesion than upon the stage of it. The indications in this respect are initial and medium stages of various cardiac affections. Moreover it is essential that the patient should observe during the entire time of his bath treatment certain regulations as to his whole way of living which have been evolved empirically during long years of experience by the medical profession.

Failure, therefore, is, generally speaking, as a rule due (1) to the selection of unsuitable cases (advanced stages), and (2) to injudicious behavior on the part of the patient. And yet there is a minority of cases in which success remains absent without any apparent reason—but such is the case in therapeutics generally. On the other hand it must be borne in mind that the benefit of the baths not infrequently manifests itself some time after the conclusion of the treatment—a curious but certain fact.

In the above I have only referred to cardiac lesions as they constitute the great majority of all cases that come to Nauheim for treatment. Suffice it, therefore, to add that a variety of other complaints can be favorably affected by the curative agents in vogue here, viz., neurasthenia and other nervous disorders, diseases of the female generative organs, scrofula, rickets, bronchitis, and gastric and intestinal affections.

MEDICAL RECORD.

THE PROCESSES OF COMPENSATION AND ADAPTATION IN DISEASE.

SPEAKING before the Harvey Society last year, Dr. S. J. Meltzer discussed the "factors of safety" with which the animal organism is provided in order that the varying stresses and exigencies of its existence may be met without a resulting strain upon the organs and tissues. He showed the liberality with which the organism has been treated in this respect, every organ and tissue possessing an abundance as well of structural elements to carry on its work, as of material to be acted upon in the production of energy, which, in this case, takes the form of the phenomena of life. In an article published in Volkmann's *Sammlung klinischer Vorträge* (No. 470) Professor D. Gerhardt of Basel considers an analogous subject, the processes, namely, of compensation and adaptation that appear in disease.

Whenever and wherever a lesion takes place these two factors become evident, sometimes directed by and dependent upon the exercise of the will, as when the left hand takes up the usual duties of the right, which may be injured or lost; oftener, however, quite independent of all voluntary effort, but simply in answer to the newly apparent demands upon the organs involved. In the circulatory system hypertrophy of the heart takes place as soon as the valvular apparatus is so deranged as to interfere with the normal work of the heart; such hypertrophy occurs even in the presence of a disease leading to malnutrition and to wasting of the other muscular organs. On the destruction of blood-vessels supplying a certain region collateral circulation quickly appears, actively diminishing, and often completely making up for the anemia caused by the injury or disease. Still more responsive and exact are the wonderful provisions which regulate the pressure of the blood in the vessels. With almost every change in the condition of the body new influences appear that tend to affect the local or general blood-pressure, yet the normal physiological compensation prevents any sudden or marked changes. In pathological states these regulatory provisions are tested still more rigorously, yet this only proves the high degree of competency possessed by them. Great increase in the volume of the blood, caused by therapeutic infusion; great diminution of it, due to hemorrhage; decrease in the area of blood-vessels caused by thrombosis of an important vessel, or the amputation of a limb; inflammatory changes in the circulation of a part characterized by congestion or hyperemia—all these may take place without any prolonged effect upon the general blood-pressure.

Similar phenomena are observed in the diseases of the kidneys. Recent work, for instance, has shown that even the retention of water in the body, which forms one of the most serious symptoms of some kidney lesions, is a compensatory process. The injured organ is unable to excrete the usual amount of salts, and the latter accumulate in the body fluids endangering the processes of tissue metabolism. The retention of water serves to diminish or to obviate this serious danger to the organism. The polyuria of the sclerotic kidney or of diabetes insipidus depend probably upon a like effort at adaptation to changed conditions. The diseased kidney is unable to handle the waste fluids of the body in their usual concentration, and the increase of fluid assists it in its task. Like changes of adaptation and compensation in answer to the new conditions brought about by disease are traced by the author in considering the nervous system, the alimentary apparatus, and the muscles of the body, and, indeed, these phenomena are open to the observation of every physician who tries to account for the manifestations of disease. In the article on "Darwinism and Diabetes" in the current issue of the MEDICAL RECORD, Dr. Eccles argues with much force in support of his belief that the sugar formation in diabetes mellitus also is a protective process.

Much more difficult, however, than such recognition is the attempt at explanation of the processes observed. Are they merely the changes conditioned by altered mechanical relations of the component parts of the body, or are they the result of purposeful provisions of the organism designed to meet just such situations, that may arise in its struggle for existence? In support of the first view stands the fact that the changes considered above often compensate only for the local disturbances in the body without regard to the general welfare of the organism; the hypertrophied heart performs its work successfully, but may impoverish the nutrition of the organism; the retention of water in nephritis helps to accomplish the dilution of the fluids supplied to the tissues, but may cause difficulty in locomotion, in respiration, in heart action; the increased respiratory efforts occurring in the diseases of the lungs assure proper oxygenation of the blood, but may exhaust the strength of the patient. On the other hand, enough adaptation to the purpose in view characterizes these phenomena to suggest that beyond the mere mechanical and chemical causes some subtle cell property exists that directs these changes, just as in the growth of the organism a guiding principle presiding over the development of the individual parts is evident.

Of course, no final answer to these questions can be given at present. But the fact that these closely related subjects were discussed at about the same time before such an organization as the Harvey Society in New York, and before an academical gathering in Basel, is of deep significance. It shows that the increased knowledge brought about by the development of modern scientific medicine is stimulating progress in more than one direction. On the one hand, it has done much to introduce rational procedures into the practice of the art of medicine by discovering new and effective methods

of prevention and cure of disease; on the other, it has furnished material for the growth of the philosophy of medicine, which seeks to formulate the few broad principles which would enable us to grasp and classify the numberless phenomena that go on in the animal organism in health and in disease.

PROPOSED NAVAL STATION AT THE JAMESTOWN EXPOSITION SITE.

There is a proposition before Congress to purchase the site of the Jamestown Exposition for a naval training station, but it would be wise before taking action to find out whether young boys can live in health in a place which had always been considered uninhabitable in summer. The soldiers in Camp Captain John Smith managed to get through the summer of last year with only a few cases of typhoid fever and malaria, but it was at the expense of much suffering and under restrictions which were too severe for a permanent thing. It is low ground in which proper sewerage is difficult or impossible, and it is surrounded by swamps which will require a perpetual crusade against mosquitos. On one side it is hemmed in by railroad yards, and on another by the notorious Pine Beach district, which of itself would be a menace to health and morality, for it has been denounced by both the clergy and the medical profession. The midsummer heat was so excessive that no exercises were allowed between 9 A.M. and 4 P.M., and it is not seen how training can be carried on under such circumstances, particularly as the summer season is the main reliance for drills. As deep water is fully a mile from shore, and the mud flats are exposed at low tide, it is not understood why naval men favor it—if they really do.

The price asked is $950,000 in addition to the $900,000 or so owed by the company to the United States—nearly two million dollars for land which cost the company a few thousand, and some buildings of doubtful value and needing rebuilding for naval purposes. This is a case in which it will be wise to let sanitarians investigate and be guided by them, as it would develop a serious scandal if after building a training station it were discovered that the young sailors could not be kept in health nor properly trained in the summer months.

NEW STATE COLONY FOR DEFECTIVES.

It is gratifying to announce that the Legislature has passed a bill making an appropriation of $188,475 for the purchase of 1,800 acres of land some thirty miles from New York City in Rockland County, near West Haverstraw, and four miles from the west bank of the Hudson River. The commission appointed by Governor Hughes in 1907 to select a site for the new State Colony did its work so thoroughly and so well in every respect that it may well have its action pointed to as establishing a record in such undertakings. Mr. William R. Stewart, president of the State Board of Charities, was chairman of the commission to select the site, and with him were associated Mr. Proudfit, whose legal training enabled him to give valuable advice on technical points that are always sure to arise in the purchase of property of any kind, and Mr. F. B. Kirkbride, who, we understand, wrote most of the report of the commission, a report which is a model in the arrangement of its contents and in the subject matters so fully dealt with.

It only remains now for the Legislature to pass a bill properly organizing the new colony. Its scope and purpose need to be specifically defined and an appropriation made for beginning the work of construction. Since Governor Hughes has called an extraordinary session of the Legislature to meet on May 11, it would be a good plan if the Governor would consent to make mention to the Legislature of the necessity for providing for the organization of the new colony at this time. We offer this suggestion for the reason that the new institution is along such broad and comprehensive lines, and the work of organizing it will be so great an undertaking, that the sooner it is begun the better, in order that the 1,800 to 2,000 defectives now in view to become residents of the new colony may be provided for as soon as possible.

The Practical Value of the Opsonic Index.

Ever since the critical consideration and careful experimental work has taken the place of the early unbounded enthusiasm in estimating the value of the opsonic treatment, voices have been heard that point out the many limitations to the practical application of Wright's theories. The determination of the opsonic index by the methods proposed by Wright has been especially criticized, and in the *Münchener medizinische Wochenschrift* of April 14, 1908, Saathoff gives further material that may lend strength to such criticism. He has found that the normal opsonic index in healthy individuals shows too many fluctuations to be used as a standard for comparison; thus in only twenty-six cases out of fifty-six were the results at all uniform, the rest differing to such an extent as to preclude the possibility of using them for a standard. The reasons for the differences found were apparently dependent not upon any changes or differences in the real content of the blood in opsonic substances, but in the many sources of error existing in the method used by Wright for their determination. Thus two consecutive determinations of the opsonic index were made in forty-three cases, and again the differences obtained were beyond any allowable error in experimental or practical work. The sources of these errors the author sees in the impossibility of preparing uniform capillary tubes, in the clumping of the leucocytes which hides the phagocytic cells, in the uneven sedimentation of the blood in the different capillary tubes, but especially in the biological peculiarities of the individual phagocytes, which lead to such marked differences in the number of bacteria taken up by them, that even the counting of two hundred cells cannot give useful averages. Thus the practical application of the opsonic index is seen to be greatly limited by the technical and inherent errors surrounding its determination; this, however, in no way detracts from the value of the contributions made by Wright to the theory of immunity, and it may be hoped that other methods may be discovered for finding the indications for opsonic treatment and for estimating the rate of progress made by its use in any given case.

The Clinical Picture of Chorioepithelioma.

The interesting condition variously known as chorioepithelioma, deciduoma malignum, syncitial cancer, etc., has of late received much attention from pathologists. The patients suffering from this disease, however, first seek the help of practising physicians, and good clinical studies of this condition are, therefore, of value in facilitating the diagnosis and the treatment of the disease. Such a study of a case of chorioepithelioma was made by Dr. E. Scheidemandel, and reported by him in the *Berliner klinische Wochenschrift* of April 13, 1908. His patient complained of pain in the chest, cough, and bloody expectoration. There was a history of a vesicular mole, removed by curettage a few months previous to the present illness. The patient's menstrual periods ceased two months before the onset of her symptoms, and she suffered from nausea and vomiting. Physical examination showed some diminution of resonance over the left apex of the left lung, with a few subcrepitant râles in the same area. The uterus was felt just above the symphysis. Blood was found in the expectoration of the patient, but tubercle bacilli were absent. The diagnosis of pregnancy and of tuberculosis was made. A few days later there appeared extreme cyanosis, dyspnea, and fever, accompanied by more physical signs in the lungs, which seemed to justify the diagnosis of acute miliary tuberculosis. Four weeks after admission there was some bleeding from the vagina, which was explained by a probable rupture of a varix, and was treated by light packing of the vagina with gauze. Some days later, however, the bleeding recurred, and careful examination of the vagina disclosed the existence of two bluish nodules in its wall, one of which was excised and proved to be a metastasis from a chorioepithelioma. The further treatment of the patient consisted in general strengthening measures with the administration of arsenic. The patient seemed to improve rapidly, and was soon strong enough to be out of bed. A few weeks later, however, she suddenly lost consciousness, and died in the evening of the same day. A study of the literature of the affection showed that this neoplasm is more frequently marked by metastases in the lungs than any other tumor. This often leads to the clinical picture similar to the one described above, which may very closely simulate pulmonary tuberculosis. The presence of any pathological phenomena in the genital organs, such as hemorrhages from the vagina or a suspicious increase in the size of the uterus, ought to warn the practitioner of the possible existence of a chorioepithelioma. Further interest is added to Dr. Scheidemandel's case by the findings at the autopsy. The metastases in the vagina were found to have completely disappeared, while many of the nodules in the lungs either had lost the characteristic picture of the tumor or showed newly formed connective tissue and the ingrowth of granulations, which could be interpreted only as evidence of marked reparative and healing processes.

Bacteria in Running Streams.

Inasmuch as the chemical methods of water analysis can only determine the presence and amount of organic matters in water, but cannot separate living and possibly actively dangerous organisms from dead and inactive matter, a biological examination may throw light on the potable quality of a water which is not to be obtained by chemical methods. M. Rothermundt (*Archiv für Hygiene*, Volume 65, No. 2) recently investigated the bacteria in streams. He found that as a rule the upper twenty-five centimeters of water contained more bacteria than the water beneath this level, though the number varied at times, being less when the current was rapid. He furthermore found that the number of bacteria in the uppermost twenty centimeters became less when the surface of the stream was exposed to the sun, being smallest at noon and largest just before sunrise. This diminution in the number of bacteria near the surface he attributes not to the sun's bactericidal power but to the fact that the bacteria seek the deeper water in consequence of a negative heliotropism. It may be of practical value to remember this fact when it is desired to make a bacteriological examination of a given water supply.

News of the Week.

A Proposal to Regulate Medical Expert Testimony.—The committee of the Medical Society of the State of New York appointed to confer with a special committee of the New York State Bar Association in regard to the regulation of expert testimony, has prepared the following tentative draft of a bill with this end in view: At any time in the pendency of any civil proceeding in any court in which any medical or surgical question is likely to be material, the court or any justice thereof may, or at the request of either party shall, appoint from the list made up as hereinafter provided one or more persons learned in the science of medicine and surgery, and of not less than seven years actual practice, as official experts, who shall investigate the facts of the case and give their opinion upon any such question arising in such proceedings, and make written report thereof to the court. Upon such appointment by the court, or if the parties file an agreement designating an expert for the case, the court shall issue an order for the person so appointed or agreed upon, to be served in the manner provided by law for the service of subpœnas. As soon as may be after service thereof the expert shall make such examination of the case as in his judgment may be necessary and practicable, and shall file his report as above provided. Such report shall be filed in the case, and shall thereupon be open to the inspection of either party, and such report may be read in evidence, and such expert may be called as a witness by either party at the trial. The New York Academy of Medicine, for New York City, and the Medical Society of the State of New York, acting for the State outside of New York City, shall, through committees appointed by these organizations, furnish to the court or courts in various counties, a list of names of members of the medical profession of good standing, and of not less than seven years actual practice, recommended by them as competent and expert in medicine and surgery, from which list the court may select such expert or experts as in its judgment may be required. Such official expert shall be paid out of the treasury of the county a minimum fee of $50 for the examination of, and report on, any case in question, $50 additional for the first day's attendance in court upon the case, and $100 a day thereafter while attendance is required by the court. The expert witnesses so listed may be called by any court of the State, and if called from the county of their residence the fee shall be increased to the extent of the extra expense incurred, to which shall be added a reasonable compensation for such extraordinary service and loss of time. Either party at the trial

may call other expert witnesses than those appointed or agreed upon, but at his own expense.

College of Physicians of Philadelphia.—The cornerstone of the new building of the college, in process of erection at Twenty-second and Ludlow streets, was laid with simple ceremonies on April 29. A letter of congratulation from the American Philosophical Society, and also cablegrams from Dr. W. W. Keen and from Dr. and Mrs. Wm. Osler were read. Prayer was offered by the Rt. Rev. Ozi W. Whitaker, D.D. This was followed by an address by the president of the college, Dr. James Tyson, who spoke of the successive homes of the college. The first of these was the Academy Building, which was occupied from 1787 to 1792. The second was the hall of the American Philosophical Society, which was occupied for fifty-three years; the third was the Mercantile Library, which was occupied for seven years; the fourth was the Picture House of the Pennsylvania Hospital, which was occupied for eleven years; and the fifth was the present college building, which has been occupied since 1863. The cornerstone was laid by Dr. S. Weir Mitchell, who pointed out that the college was founded in 1786 by a small group of surgeons who followed Washington in the War of the Revolution. During the War of the Rebellion 139 of the 180 Fellows of the college served on field and in hospital, on land and at sea, in the service of the country. A benediction was spoken by Bishop Whitaker. The new building, which, it is expected, will be completed in a year, will cost in the neighborhood of $300,000. It will be two stories high, of red brick and light-colored limestone, and it will be fireproof. The floors and panels of the walls will be of marble. In the evening Dr. Mitchell gave a dinner to the officers of the college, the council, and the building committee.

Two Hundred and Twenty-fifth Anniversary of the Founding of the City Government of Philadelphia.—In connection with the celebration of the two hundred and twenty-fifth anniversary of the founding of Philadelphia a "Medical Day" has been arranged for, at which addresses will be delivered by eminent medical men from many sections of this country and from abroad. Among the speakers will be Professor Pearsoll, of the University of Pennsylvania; Dr. J. Chalmers Da Costa, professor of surgery in Jefferson Medical College and Hospital, and Dr. J. M. Anders, professor of the practice of medicine in the Medico-Chirurgical College and Hospital. The medical schools and hospitals are arranging to have clinics, lectures, and demonstrations for the benefit of medical visitors, and a volume of 1,000 pages is to be issued containing an account of all the historical institutions, colleges, medical and scientific societies and journals, and hospitals that have existed in the city since its founding.

Pollution of Sources of Ice Supply.—In a bulletin issued by the State Health Department, Commissioner E. H. Porter reports the results of an investigation of the Hudson and Mohawk River icehouses and fields and the sources of ice pollution along the Hudson from Troy to Catskill and along the Mohawk from Schenectady to Cohoes, made by the department's sanitary engineering division. The report states that zones of dangerous pollution in the waters of the Hudson and Mohawk rivers, from which ice is harvested, exist in the vicinity of Albany, Troy, Schenectady and other places along the upper Hudson and lower Mohawk valley, and that there are forty-one icehouses in this vicinity which are so located with reference to sewage outlets as to render their ice subject to contamination and therefore a menace to health.

Plague.—The Porto Rican Board of Health has petitioned the Federal authorities to establish a quarantine against Venezuelan ports and neighboring islands that have not taken proper restrictive measures, and also to furnish a naval vessel for the purpose of guarding the Islands of Vieques and Culebra, where smuggling is frequent. Disease has been introduced into Porto Rico on previous occasions through these islands. Money has been allotted by the Board of Health for precautionary measures against the plague, and for the purchase of antiplague serum. Passengers arriving in San Juan from Venezuela are quarantined. Curaçao has also established a quarantine against Venezuela.

Smallpox in Chicago.—Ten patients suffering with smallpox were sent to the Isolation Hospital during the week ending April 25. Of this number three were from Evanston, Illinois. Eight of the patients contracted the disease from the same source, namely, an unvaccinated colored boy with a mild type of the disease. According to the Chicago Bulletin of Health, at the present time there are fifteen cases of smallpox remaining at the hospital.

For Safety Devices on the Street Cars.—The Public Service Commission has begun an investigation into the character and efficacy of the safety devices provided on the street cars of the city, with a view of attempting to lessen the number of deaths and injuries caused in street accidents. The commission has directed all the traction companies to file before May 10 complete statements as to the number and kinds of cars owned, and the detailed equipment of those cars. The statistics of the commission show that in the six months ended February 1, 1908, the street railways of Greater New York killed 299 persons and seriously injured 944. The total number of accidents due to collisions of street cars was 1,196, and the number of vehicles and persons struck by cars was 7,059. At this rate in an entire year about 600 persons would be killed and 2,000 seriously injured. The number of accidents due to collisions would approximate 2,400, and the number of persons and vehicles struck 14,000, a condition urgently demanding amelioration.

Physicians and Druggists to Study Pharmacology Together.—Recently a joint meeting of the Evanston Branch of the Chicago Medical Society with the druggists of the vicinity was held for the purpose of discussing nostrums, counter-prescribing, incompatibilities, and other matters of interest. There was organized, as the outcome of this meeting, the Evanston and North Shore Pharmaceutical Society, whose object is to study the composition, preparation and action of drugs. Licensed physicians and registered pharmacists of Cook County, north of Chicago, are eligible for membership.

An Emergency Hospital in Chicago.—Health Commissioner Evans of Chicago will soon open an emergency hospital on the second floor of 129 Harrison street, to be in charge of Dr. Geo. C. Hunt, now chief of the ambulance service.

Gift to Michael Reese Hospital of Chicago.—Mr. Gustav Freund has given to this hospital, as a memorial to his parents, the southeast corner of Groveland avenue and Twenty-ninth street, a plot fifty and one-half by ninety-six feet. In view of this gift, the building now on the ground is to be improved and used by the hospital as a home for nurses.

Gift to Harvard Medical School.—Harvard Medical School has received through Dr. Walter G. Chase from the Royal College of Surgeons of England a collection of seventy engravings and mezzotints of celebrated medical men. These, together with loan collections of Dr. Chase and Dr. E. B. Young, numbering about six hundred, have been arranged for exhibition in the Warren Anatomical Museum, in the administration building of the Harvard Medical School, Longwood avenue.

An Appendicitis Wave.—It is reported from Temple, Tex., that during the last two weeks of April there have been more than fifty operations for appendicitis in the town.

Lister's Birthplace.—A bronze tablet is to be placed on the house in Upton Lane, Forest Gate, West Ham, London, now St. Peters Vicarage, in which Lord Lister was born.

Advertising Specialists to Be Prosecuted.—It is announced that the prosecutor of the city of Chicago will undertake to prosecute those physicians and business houses that advertise cures for certain diseases and weaknesses. According to the ordinance, fines vary from $25 to $200 for conviction in such cases.

Dr. James Herbert McKee has been elected professor of pediatrics in the Medical Department of Temple University at Philadelphia.

Dr. John B. Murphy of Chicago recently resigned his position as Professor of Surgery in Rush Medical College, and has since accepted the Professorship of Surgery (head of the department) in the Northwestern University Medical School, as well as the position of attending surgeon at Mercy Hospital. Dr. Weller Van Hook, who formerly held the chair of Professor of Surgery in the Northwestern University Medical School, has resigned.

Hampden District (Mass.) Medical Society.—This society met in Springfield on April 21 and elected the following as officers: *President*, Dr. George L. Woods of Springfield; *Vice-President*, Dr. C. W. Jackson of Monson; *Secretary and Treasurer*, Dr. R. S. Benner of Springfield.

Worcester North (Mass.) Medical Society.—The fiftieth annual meeting and semicentennial celebration of this society was held in Fitchburg on April 28. The following officers were elected: *President*, Dr. John G. Henry of Winchendon; *Vice-President*, Dr. Eustace L. Fiske of Fitchburg; *Secretary*, Dr. Walter F. Sawyer of Fitchburg; *Treasurer*, Dr. Eustace L. Fiske.

The Medical Association of the Southwest will hold its next annual meeting in Kansas City, Missouri, October 20 and 21, 1908. The association is composed of members from the following five States: Kansas, Arkansas, Oklahoma, Texas, and Missouri. The secretary is Dr. F. H. Clark, of El Reno, Oklahoma, and Dr. John Punton, 532 Altman Building, Kansas City, Missouri, is the chairman of the committee on arrangements.

The Northern Medical Association of Philadelphia held its sixty-second annual banquet on the evening of April 29. Dr. Francis X. Dercum spoke on "Fads in Medicine"; Dr. Max. J. Stern on "Fancies and Humor in Medicine," and Dr. John W. Millick on "The Old and the New."

National Confederation of State Medical Examining and Licensing Boards.—This organization will hold its annual meeting in Chicago, Ill., on Monday, June 1, 1908, under the presidency of Dr. Geo. W. Webster of Chicago. The secretary and treasurer is Dr. Murray G. Motter, of 1841 Summit Place, Washington, D. C.

American Medico-Psychological Association.—This organization, formerly entitled the Association of Medical Superintendents of American Institutions for the Insane, will hold its sixty-fourth annual meeting in Cincinnati, May 12, 13, 14 and 15, 1908, under the presidency of Dr. Chas. P. Bancroft, of Concord, N. H. The secretary and treasurer is Dr. Chas. W. Pilgrim, of Poughkeepsie, N. Y.

National Association for the Study of Epilepsy and the Care and Treatment of Epileptics.—The annual meeting of this society is to be held at Indianapolis, Indiana, on Tuesday and Wednesday, November 10 and 11, 1908, under the presidency of Dr. H. M. Weeks, of Spring City, Pa. Those desiring to attend the meeting and present papers should communicate with the secretary and treasurer, Dr. J. F. Munson, the Craig Colony for Epileptics, Sonyea, N. Y.

Springfield (Mass.) Academy of Medicine.—The second annual meeting of that body was held on April 14 and the following officers were elected: *President*, Dr. W. A. Smith; *Vice-Presidents*, Dr. John A. Houston of Northampton, and Dr. R. J. Seelye; *Secretary*, Dr. J. I. Butler; *Treasurer*, Dr. H. W. Van Allen.

Litchfield County (Conn.) Medical Association.—At the one hundred and forty-fourth annual meeting of this society, held in Winsted on April 28, officers were elected as follows: *President*, Dr. L. L. Hamant of Norfolk; *Vice-President*, Dr. S. G. Hurd of Winsted; *Clerk*, Dr. F. H. Lee of Canaan.

South Idaho District Medical Society.—At the meeting of this organization held in Boise on April 14 the following were elected as officers: *President*, Dr. J. A. Young of Caldwell; *Vice-President*, Dr. C. L. Dutton of Meridian; *Secretary and Treasurer*, Dr. F. H. Brandt.

Plymouth District (Mass.) Medical Society.—At the meeting of this society held in Brockton on April 15 these officers were elected: *President*, Dr. Fred J. Ripley; *Vice-President*, Dr. Charles S. Millet; *Secretary and Treasurer*, Dr. A. C. Smith.

Bristol North District (Mass.) Medical Society.—At the meeting of this society held in Taunton on April 16 officers as follows were elected: *President*, Dr. Elliot Washburn; *Vice-President*, Dr. A. V. Goss; *Secretary*, Dr. R. D. Dean; *Treasurer*, Dr. W. Y. Fox.

Tulane Alumni Association.—The Tulane Alumni Association announces that it is important that all graduates of Tulane University intending to be present at the meeting of the American Medical Association in Chicago, June 2 to 5, should write at once to Dr. Hugh B. Williams, 100 State street, Chicago, for information concerning the gathering of the alumni on June 2. Tulane headquarters will be at the Auditorium Hotel and alumni are urged to call upon their arrival for information.

The Woman's Medical Society of the State of New York is the name of a new society, papers incorporating which were filed with the Secretary of State at Albany on Saturday last. Among the incorporators are Drs. Mary H. Cotton of New York City, Mary I. Denton of Buffalo, Sarah B. Dolley of Rochester, and Florence A. Sherman of Watertown.

Harvey Society Lecture.—The tenth and last lecture in the Harvey Society course will be delivered at the New York Academy of Medicine on Saturday, May 9, at 8:30 P.M., by Prof. A. E.

Schäfer of the University of Edinburgh, the subject being "Artificial Respiration in Man." Prof. Schäfer, who has come to the United States for the purpose of giving the Herter lectures at the Johns Hopkins Medical School, was chairman of a committee appointed by the Royal Medical and Chirurgical Society to investigate the phenomena attending death by drowning and the means of promoting resuscitation in the apparently drowned. His lecture will embody the results of much practical work on the subject of artificial respiration.

Supreme Court Decision Regarding Vaccination.—It is said that the Supreme Court of Illinois has declared that the State law which makes vaccination compulsory is unconstitutional.

Death of Prof. Chamberland.—Professor Chamberland of Paris, the well-known subdirector of the Pasteur Institute and a member of the Académie de Médecine, died on May 2 at the age of fifty-seven years. He was the originator of the widely used porcelain filter which bears his name.

Death of Sister Louis Gonzaga.—At a recent meeting of the medical board of St. Vincent's Hospital the following resolution was adopted: After many fruitful years of continuous, abundant, and merciful labor in the cause of the poor and the suffering of the city, Sister Louis Gonzaga has passed along from an honored post of earthly duty to one of exalted station of reward in the world above. Those who, heretofore, have been cheered by her gracious presence and genial smile, ever an earnest of beneficent desire and of a pure and humble spirit, will miss her benign presence and bountiful benevolence more and more as time endures. Sister Gonzaga's devotion to duty was not limited by measure nor modified by method; it was free and boundless. Her activities were tireless, and the products of her efforts were worthy of the emulation of those having the sincerest motives and the largest benevolence. Sister Gonzaga believed in friends implicitly and heeded their advice with discreet and trustful reliance. She resented wrong with vigor, pardoned error with joy, and welcomed truth with open arms. Sister Gonzaga's devotion to duty should inspire us all to broader efforts and higher aims in every field of worthy opportunity, so that, like her, we too can reap the rewards commensurate with righteous achievements in every path of duty. Constantine J. MacGuire, M.D., chairman; Edward L. Keyes, Jr., M.D., secretary.

Obituary Notes.—Dr. James Edwards died at Morton, Pa., on April 28 at the age of eighty-eight years. He was a graduate of Jefferson Medical College.

Dr. Edward Dodd, of North Babylon, L. I., died on April 28 of pneumonia at the age of sixty-nine years. He had served in the Civil War and practised for many years in North Babylon. Some years ago he retired from active practice.

Dr. Alexander Cochran of Brooklyn died on April 29 at the age of seventy-seven years. He was born in Ireland, but came to this country in early life, and was graduated in 1855 from the College of Physicians and Surgeons of New York. He served as surgeon in the Eleventh Brigade in the Civil War, and was an inspector in the old Health Department of Brooklyn for several years.

Dr. James J. Terhune of Brooklyn died of nephritis on April 30 at the age of sixty-four years. He was graduated from the Long Island College Hospital in 1875 and had since been in active practice in Brooklyn. He served in the Civil War in a New Jersey cavalry regiment, and was a member of U. S. Grant Post, G. A. R. He had been surgeon of the Thirteenth Regiment for several years.

Dr. William H. Caswell of this city died at Shelter Island on May 3 at the age of sixty-six years. He was graduated from the College of Physicians and Surgeons in 1888 and had made a specialty of neurology.

Dr. Richard Stebbins of Omaha, Neb., died suddenly on April 19 at the age of eighty-four years. He was a native of Springfield, Mass., and was graduated from Harvard in 1846. He practised for a time in New York City and various Western cities, later settling permanently in Omaha.

Dr. James C. Ralston of Pittsburg died on April 27 as the result of a streptococcus infection received in the course of his work as pathologist to the Pittsburg Hospital of the Sisters of Charity.

Dr. Gustavus Hay of Jamaica Plain, Mass., died on April 26 at the age of seventy-eight years. He was born in Boston and was graduated from Harvard in the class of 1850, receiving his medical degree from the same university seven years later. He made a specialty of ophthalmology and otology and had held many positions in Boston hospitals.

Dr. Frank P. Moore of Lisbon, O., died of tuberculosis in San Antonio, Texas, on April 14, at the age of fifty-seven years. He was born in East Fairfield, O., and was graduated from the University of Michigan medical school in 1874, since which time he had practised in Lisbon.

Dr. Charles J. Towne of Essex, Mass., died on April 22, at the age of sixty-eight years. He was born in Stoddard, N. H., and received his medical degree from Dartmouth. After practising for a time in Townsend, Mass., he removed to Essex in 1878.

Dr. Carl Kitchen of Des Moines, Ia., died on April 23 at the age of fifty-eight years. He was born in Indiana, and in 1878 was graduated from Keokuk Medical School.

Dr. Anthony White of Excelsior Springs, Mo., died on April 20, at the age of sixty-two years. He was born in Germany, but was graduated from Rush Medical College, Chicago, in 1889.

Correspondence.

OUR DUTY TO THE CRIMINAL.

To the Editor of the Medical Record:

Sir: In *Charities* for March 14, 1908, the writer calls attention in a timely manner, as I believe, to several directions in which some of our penal institutions may be greatly improved, especially our county jails and penitentiaries.

In the first place, I insist upon the importance of daily food inspection by competent and reliable men, entirely outside and above all political affiliations. I also believe, and rightly so, that food for prisoners should be properly served—not, as is often done, in rusty tins, cold, unpalatable, and eatable only under the pressure of dire hunger. Medically speaking, how can the bodies of men be thus preserved? Morally, is it for their present or future welfare? Are taxpayers willing continuously to pay the price of food which prisoners do not always get? It should be for the New York State Prison Commission to investigate and to report their findings, so that, if necessary, the Governor, and, perhaps, finally, the courts, may decide what is best to do about it.

I desire, and again rightly, that every penal institution should have an advisory medical board, nonsalaried and above reproach. The advisory medical board should be selected from men who have grown gray in service, good and true to their fellow men, who will do essential work for prisons and prisoners, besides caring for the ill, and who, whenever and wherever matters, sanitary and even moral, call for action, will stand firm for right. After all is said, *morality* often depends upon the *sanitary*, and therefore the

physician should have *real* and *not perfunctory* control. Is it permissible to have merely one physician to a prison, and he salaried and possibly a political appointment? Let him interfere too much with the reigning powers, as they could affirm, and his position might be lost, or, at least, the risk thereof would be great. Who should see and know and have power every day except he, to do his full duty as a man and physician, when other men and brethren, for little wrongdoing, may be thrust into "coolers," namely, into damp, dark, cold cells for one or several days, in solitary confinement, with insufficient covering—a gill or two of water and a slice or two of bread allowed per diem—to breathe an irrespirable air due to insufficient ventilation and also to body exhalations and excretions, almost unbearable at times for man or beast—a positive proof of "man's inhumanity to man."

How may we, how should we further correct all this? Only by official visiting—visiting by those well selected and approved, who will instruct and guide, who will speak of integrity, duty, truth, work—the essential things Jesus Christ came to teach men here below. Let us have creeds of many kinds if we will, but let the underlying thought of all creeds for the guidance of life stand out and far above all of them. When jails, penitentiaries, prisons, and even so-called reformatories have for wardens or superintendents, not, as is true sometimes, men of low ideals, imperfect knowledge, strong bias for "pull and place," and not for right and duty, but invariably the instructed, humane, merciful ones of earth, then penal institutions might reform prisoners, and not breed continuously, as they do now, not a few worse, and, indeed, fresh criminals.* I would venture to add that anarchists and socialists would then also be greatly reduced in number.

BEVERLEY ROBINSON, M.D.

42 WEST THIRTY-SEVENTH STREET.

CORRECTION OF UTERINE DISPLACEMENTS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR—It seems a work of supererogation to answer Dr. Byron Robinson's criticism of my "Plea for the Correction of Uterine Displacements." Quoting his statements will suffice, in many cases, to refute his arguments. His answer to his own question as to the normal position of the uterus, that "it is a perfectly movable one," is an instance. Of course, it should be a perfectly movable one, and for that reason I object to leaving it "lying upon the rectum," or in the sacral hollow, pinioned beneath the intestines, sustaining their weight upon its face, and the transmitted pressure of corset and heavy skirts.

Dr. Robinson says, "A fixed uterus is pathological, and will be injured in its functions, absorption, menstruation, secretion, gestation, etc." I agree with him as to that, too, and for that reason I wrote my "Plea for the Correction of Uterine Displacements." His simile of "loose testicles requiring no fixation" is, of course, hyperbole, the uterus and testicles bearing about the same relation to each other in structure, function, and position, as the objects looked at respectively through the microscope and the telescope. He says that uncomplicated retroversions do not need treatment, notwithstanding his previous statement that the normal position of the uterus was a "perfectly movable one." However, if that were true, the fact is that they do not *remain* uncomplicated, as I tried hard to demonstrate in my paper. Dr. Robinson dismisses my arguments without discussion, but I do not agree that that disposes of them. I repeat that when the fundus of the uterus goes back to the sacral hollow, the drainage received from the tubes, gathered from the pelvis by the fimbriæ, as has been proven by experiment, can no longer be passed into the vagina, and collects in this inverted bowl. Not only does this collection render the uterus foul, but the current in the tube is eventually reversed, and the accumulation is returned to the pelvis. Slowly and inevitably inflammation, congestion, and hyperplasia ensue, succeeded by perineal heaviness, dragging sensations, pelvic uneasiness; and then these belated surgeons begin to recognize retroversions with complications, and are ready to render assistance. They do not, or they seem not, to understand that assistance rendered earlier might have prevented these complications. They would confine preventive treatment to the bacterial diseases. They would give antitoxin after the jaw is locked, and the back is arched, the destruction of the nerve centers has already occurred.

I am not willing to leave the uterus helpless in the sacral hollow, awaiting the results of plastic changes that compel assistance. I want to set it up when I can do so with my two hands, sustaining it if necessary with a pessary. By thus continually replacing it, I have succeeded in restoring it permanently to that normal position of "perfect mobility," which Dr. Robinson describes, and without even the aid of tampons. And in these simple cases, pain and other symptoms have been relieved. One woman, beyond sixty, having passed the climacteric some twelve years before, complained of pain and leucorrhea. She was gray and wrinkled, her breasts were atrophied, muscles attenuated, she stooped, and in every way bore the marks of old age. Her uterus was retroverted, "lying on the rectum," large and boggy. After several corrections, it remained upright, and several months later was found—as observed both by Moncure and myself—to have atrophied, to have joined the other organs in senility.

I defy Dr. Robinson's assertion that my paper was a bid for surgery. Many of my patients, when I can get the uterus off the rectum, I treat from day to day, setting the organ up as often as it falls, and often succeed, almost beyond my heart's desire, because it is a pleasure to look in the pelvis, perhaps to verify your own diagnosis. "Hysteropexy" is not considered a "short road" or any "road to success" in fruitful women. It has been abandoned. But that operation is preferable to leaving the uterus resting on the rectum, pulling and tugging upon the broad ligaments and ovaries, pressing upon the sacral nerves and their sympathetic ganglia, the sacral plexus, the superior and inferior hemorrhoidal plexuses, giving rise to constipation by directly encroaching upon the rectum, and indirectly, through the interruption of nervous impulses; irritating the pelvic nerves, and, incidentally, bringing about universal nervous disturbance. The "hyperemia" that the uterus enjoys while retroverted, and which Dr. Robinson so much lauds, bears this distinction to the Bier treatment, to which he evidently refers, in that it is constant. Professor Bier never contemplated the constant application of a bandage above a tuberculous knee, or the induction of a permanent congestion in any organ or tissue, but in every instance removes the stricture some time during the twenty-four hours, and allows the accumulated blood to pass.

FRANK H. HANCOCK, M.D.

NORFOLK, VA.

*See in *Charities and the Commons*, March 21, 1908, report of committee appointed to investigate jails and penitentiaries.

THE RAY BROOK SANATORIUM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR—The letter of Dr. Macdonald in your issue of April 18, while an arraignment of the New York State Civil Service Commission and its methods, is so manifestly unfair by the reflections cast upon the qualifications of the men certified by the Commission as to demand reply.

It is true that the examination held last May for the purpose of securing a list of eligibles for the Superintendency of the Ray Brook Hospital was devoted largely to a discussion of Wright's opsonic hypothesis and its relation to the diagnosis and treatment of tuberculosis. I "read" for the examination, as I have no doubt the other candidates did also, but certainly there is nothing unusual or remarkable about this. Whether the opsonic theory and the use of sera have any practical application in the treatment of tuberculosis is not the question at issue. A year ago the subject was occupying the attention of phthisiotherapists the world over, and these questions, if they served no other purpose, were calculated to determine whether a man who aspired to be the head of a tuberculosis hospital was familiar with the most recent theories and discoveries in connection with the disease. If these questions had their origin in the mind of the lay chief examiner he is indeed a genius. However, the *New York Times*, in the issue of March 22, in discussing the Ray Brook situation, states that they were prepared by Dr. Samuel B. Ward of Albany. He is the gentleman who prepared the examination held some two years ago, when the man appointed as Superintendent had the favorable consideration of the Board, and it is not understood that there was any criticism of this examination, although the subject of sera was pretty thoroughly discussed.

Dr. Macdonald intimates that our knowledge of the diagnosis of pulmonary lesions, in their various stages, was gained simply by reading textbooks. Because the examination gave us no opportunity to demonstrate in a practical way our capacity as experts in the physical diagnosis of incipient phthisis, it is not just to infer that our knowledge of this most important subject is purely theoretical. I submit that there are men not connected with tuberculosis hospitals who are expert in the diagnosis of incipient pulmonary lesions "through prolonged, varied, and practical experience."

He states "that there are a large number of men who seek to improve their position financially and socially

largely through their capacity to prepare and to successfully pass Civil Service examinations as now conducted in the State of New York." It is not understood how surgeons of the Army or of the Marine-Hospital Service could hope to improve their social position by occupying any position obtainable in the State of New York by passing a Civil Service examination. When the Doctor remarks that men trained for the service of the United States Army or the "Marine Corps" (*sic*) of the United States present no conclusive evidence that they should be made superintendents of tuberculosis hospitals he evidently forgets that two of the most successful hospitals of the kind in the world are maintained in New Mexico, one by the Army at Fort Bayard, and the other by the Marine-Hospital Service at Fort Stanton, and that both institutions are successfully managed by men trained only in their respective branches of the public service.

He remarks that the action of the Board in causing to be introduced in the Legislature a measure reducing the post-graduate experience required of the candidates from six to five years was taken in order that a certain man might be made eligible, *not for appointment*, but for the Civil Service examination. Yet the Doctor told me in the Albany City Hospital last January, in reply to my inquiry as to what they were going to do, that the Board intended to have the law changed and *appoint* the man referred to. I was also informed to the same effect by the Rev. Dr. Devins, the Secretary of the Board. In view of this attitude of the Board, it is not likely that any one cognizant of the state of affairs will put himself in the position of competing with a picked candidate, in case another examination is held, notwithstanding the appeal for publicity of the fact that the Superintendency of the Ray Brook Hospital is now vacant. The impression is firmly fixed in the minds of those familiar with the situation that the Board has held the vacancy open for the past year in order that their candidate, "who has served the institution for a number of years," would be eligible under a five-year post-graduate requirement; and that had this candidate not been denied admission to the examination held by the Civil Service Commission last May there would have been no fault found with the questions or with the method of conducting the examination.

The Doctor complains that the examination last spring was held "without any consultation with the Board of Trustees as to their notions of the attainments necessary for the Superintendency at Ray Brook." This attacks the basic principle of civil service reform, which contemplates a distinct separation of the appointing power and the examination. If the Civil Service Commission is incapable of obtaining a suitable man for the Superintendency of the Ray Brook Hospital (which is not admitted), then, for goodness sake, exempt the place from the provisions of the Civil Service law, and let us have no more opera bouffe examinations.

V. E. Watkins, M.D.,
Contract Surgeon, U. S. Army.
No. 2 on the List of Eligibles.

MELODY CURE OF STUTTERING.

To the Editor of the Medical Record:

Sir—The letter of Dr. Rosenbeck in your issue of April 18 claims priority for the "melody cure" of stuttering on the part of a writer in 1588, who recommends singing as a cure. The melody cure is in no way related to singing. The stutterer (or stammerer) never stutters while singing, but any amount of singing will never stop his stuttering when he talks. The melody cure is based, in the first place, on the fact that every stutterer speaks in an abnormal voice, which is characterized by monotony and stiffness, and, in the second, on the fact that he ceases to stutter as soon as he learns to speak in a melodious voice. The cure consists simply in training him to speak melodiously, not to sing. Neither the observation concerning the stutterer's monotony nor the attempt to replace the lost melody have, as far as I can learn, been made before my work was begun at the Vanderbilt clinic. I must add that the melody cure differs from other cures in vogue in that it is based on no such tricks as lengthening the vowels, dropping consonants, etc., all of which distort the speech. It simply brings back to normal action an organ that was acting abnormally. This is the reason why the cure is invariably successful and permanent.

OUR LONDON LETTER.

From Our Special Correspondent.

CANCER RESEARCH IN THE COLONIES—SIR A. WRIGHT'S LUMLEIAN LECTURE—ANESTHETICS—BENEFICENT BACTERIA—HOSPITAL SATURDAY FUND—OBITUARY.

London, April 17, 1908.

Last night a White Paper was issued dealing with cancer research in the Colonies. The attention of the authorities in the British Colonies and Protectorates had been drawn to the importance of these investigations being on a uniform basis, as great interest is attached to the occurrence of cancer in widely separated geographical areas and in divergent races. Valuable information had already been obtained and attracted notice in foreign countries where equal opportunities for such expensive investigations did not exist. Special attention was directed to the microscopical examination of tumors, and it was pointed out that inquiries lately conducted in England, Scotland and Ireland had shown that with the great facilities enjoyed at home almost 40 per cent. of the less advanced cases of internal cancer and many external cases were not recognized in hospitals from clinical symptoms alone, and a large number of cases would have been ascribed to cancer had not microscopical examination shown them not to be so. In different parts of the Empire this examination was important, not only as to the variations of the records, but also on account of the uncertain nature of many diseases common in the tropics. The difficulties medical officers had to contend with in discovering cancer in aboriginals are fully recognized, but it is added that where the requisite evidence is difficult to obtain it possesses most value. In replies received to the circular letter the Acting Governor of Barbados remarks on the apathy of the medical profession and reports an effort to awaken their interest in the subject. The Governor of St. Helena mentions that the Acting Colonial Surgeon suggests that tubes should be dispatched for sending home specimens. The chief health officer of Tasmania suggests the regular transmission to the colonial medical authorities of the diagnosis made in England of any case sent which commanded more than ordinary attention.

Sir A. E. Wright delivered the Harveian Society's lecture this year and naturally devoted it to the importance of taking the opsonic index in connection with therapeutic immunization. The determination of the opsonic index both before and after inoculation would, he maintained, always serve as a guide to dosage. If the determination were not made, only the smallest amount could be safely administered, and that might not be sufficient to produce the beneficial effect. Moreover, the index is the most useful guide to the time for giving the remedy. The dangers of too large doses were seen when tuberculin was first introduced. He admitted that in some cases the dosage may be measured to a certain extent by the local effects, or even by the pyrexia, but for accuracy the opsonic index is the only reliable guide. Thus in staphylococcus infection with local lesion, as in boils or carbuncles, the local effects can be seen and serve as a gauge to dosage, and the same may be said as to some cases of tubercle of the skin. In regard to pyrexia the lesion is often unhealed, although the temperature has returned to normal, and then the opsonic index is the only guide. This remark applies particularly to the treatment of pulmonary tuberculosis. In other chronic cases the index is the essential guide as to the time of making inoculations as well as to the amount to be injected, and the same may be said of cases without visible lesion and where symptoms are latent. In acute cases time is important and too large a dose dangerous, so the index must be determined. The lecturer proceeded to point out two important points as to inflammation, viz., the emigration of leucocytes and the transudation of lymph, laying down that it is important that (a) there should be a plentiful supply of blood and lymph to the part, (b) that these should carry protective substances, and (c) that a full supply of healthy leucocytes should reach the part. Sir A. Wright then gave instances of what he called "miscarriage of inflammation." These are (1) where there is excessive serous effusion with too few leucocytes, as in tuberculous pleural effusion; (2) in abscess formation where the leucocytes are dead, the protective substances absent, and where the fluid containing the disintegrated leucocytes has an injurious effect on the healing process; (3) where a sinus or fistula is produced or great induration around the lesion; (4) where excessive dryness of the tissues hinders the access of

the protective substances. These miscarriages can be remedied by appropriate methods. Thus when fluid is in excess we can remove it; in the opposite condition we can increase the flow by applying citrate and chloride of sodium to the part or even by giving acid citric internally, and, more important still, we can increase the protective substances by inoculations of the proper vaccine in accurately determined doses.

For the last two months or more the subject of anesthesia has occupied attention from various points of view. One of these is the responsibility of anesthetists, and this has been freely discussed before the Medico-Legal Society, which has adopted resolutions addressed to the General Medical Council and the Privy Council urging that definite instruction on the subject should find a place in the curriculum, and that only registered practitioners should be permitted to administer anesthetics. Not much objection will be taken to this procedure and the bodies concerned will no doubt prolong their consideration of it as inordinately as usual. Meantime what is the actual legal liability of the anesthetist is a question of no little importance. It was considered at the Medico-Legal Society and the president—no less an authority than Mr. Justice Walton—made some weighty statements. He said, for instance, that if a surgeon killed a man by operating on him it was not an absolute excuse to say he had done his best. With regard to inquests which had been discussed Mr. Justice Walton said the law was simple; the difficulty arose from the facts. A coroner must hold an inquest if he had reason to think the death was unnatural. To apply that to chloroform in the ordinary course of practice—was such a death unnatural? He would not deal with it now. Some day it might come before the courts. If death from chloroform was unnatural, and the coroner had reason to think that the cause of death, he must open an inquest. So if death was by an operation that seemed unnatural. In regard to restricting the administration to registered practitioners, he was of opinion that the only persons distinctly forbidden to practise appeared to be apothecaries. To do the work of physician or surgeon was not in itself a penal offense, but to practise as apothecary was, though he could not say why. So a man might perform operations or give medicines without committing a penal offense provided he did not practise as an apothecary, whatever that might mean. But if he killed anybody and was not qualified it would not be sufficient excuse for him to say he had done his best if he had been doing something which was in itself dangerous and likely to cause death unless done with great skill, and he knew he had not that skill. In such a case he thought it would be obviously manslaughter and probably murder.

The state of the law as thus expounded by one of our legal luminaries is to say the least unsatisfactory.

"Beneficent Bacteria" was the title of a lecture given at the Institute of Hygiene on Tuesday afternoon by Dr. J. W. H. Eyre. Having gained attention by some striking figures, such as that nearly ten millions placed end to end would only measure a yard, and that one hundred millions would be required to cover a shilling in a single layer, and that in eighteen hours one could increase to 76,456 millions, Dr. Eyre proceeded to show how useful and necessary these organisms were. The part they played as nitrogen fixers was now becoming known to the farmer, who can be supplied by laboratories with cultures to inoculate his fields at sowing time. The utilization of lactic bacteria by dairymen was explained and also the action of the septic tank for dealing with sewage. Other examples of beneficent bacteria were given, and the frequenters of the Institute are to be congratulated on their presence.

The Lord Mayor presided on Saturday afternoon at the annual meeting of the Hospital Saturday Fund. The income for 1907 was £27,140, being an increase of £680 on that of 1906. The twenty-three local committees collected £3,529 and £105 was received from football competitions. On January 18 £24,437 was distributed among 208 institutions. During the thirty-four years of the fund's existence over £400,000 has been raised in London mainly by the workingmen. The Lord Mayor said that, notwithstanding the discontinuance of street collections since 1897, the receipts of the fund had increased each year and a debt on the purchase of the freehold offices had been paid off. He called attention to the fact that not only hospitals, but dispensaries, convalescent homes, and surgical aid societies benefited by the fund. The Mayor of Southwark also spoke and said every firm having twenty employees should hold a collection. The Lady Mayoress distributed medallions to the St. John's Ambulance Association.

The death of Thomas Henry Wakley on the 5th inst. at the ripe age of 86 removes another medical editor of the last generation. He was the son of the founder of the *Lancet* and for some twenty years a joint editor with his younger brother James, who predeceased him by many years and whose career had practically been restricted to the *Lancet*.

The recently deceased Thomas Henry took the membership of the College of Surgeons in 1845, the Fellowship in 1849, and became surgeon to the Royal Free Hospital. Throughout the fifties he was much occupied with the subject of stricture, for the treatment of which he devised an instrument. He wrote some articles for Cooper's Surgical Dictionary, but his contributions to medical literature were mostly in the *Lancet*. He leaves a son, who is also at work on the journal.

Dr. Oswald A. Browne, F.R.C.P., A.M., M.D. (Camb.), assistant registrar of the Royal College of Physicians, died on the 9th inst. He took his first diploma, M.R.C.S., in 1881, that of the Lister College in 1886, and was made a Fellow in 1898. He was physician to the Royal Chest, the Alexandra Childrens', and the Metropolitan hospitals. He contributed some papers to St. Bartholomew's Hospital reports, at which hospital part of his education was taken.

Dr. Joseph Walker, formerly president of the Odontological Society, died on Monday at midnight in his eighty-third year. He took the M.R.C.S. and L.D.S. in 1860 and subsequently M.D. (St. Andrews). He had been on the staff of the Dental Hospital and lectured on mechanical dentistry there, and had also taught dental surgery at the Westminster Hospital. He was editor of the Journal of the Dental Association and of the Transactions of the Odontological Society, 1880-1882, and a contributor to these, as well as to the medical journals.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 23, 1908.

Orthopedic Heresies on Feet and Their Treatment.—The profusely illustrated paper of L. R. G. Crandon is an amplification of the following propositions: (1) The foot has adapted itself to vicious shoeing conditions and has become a hind-foot or hoof. (2) Acute foot symptoms are only a part of general muscular flabbiness and ligamentous relaxation. (3) Chronic foot symptoms are due partly to general lack of tonicity and partly to vicious shoes. (4) The reason that some patients get well using plates is that they develop muscles trying to get away from the uncomfortable plates. (5) Modifications of the plate idea are equally bad. (6) The fallacy of footprints and plaster casts as means of diagnosis. (7) Treatment. The education of the patient in standing and walking. The author elaborates the principles of proper shoeing and gives the histories of illustrative cases. The good shoe is defined by him as one which is light in weight, soft and flexible in all its parts, and the flat heel should be rendered balancing and unstable by making the outer front corner of soft rubber. The construction should be such that in size and shape the shoe shall not pinch the expanded foot bearing all the weight of the body, and the inner sole so made that the foot shall not after a short time sink down in the middle of the plantar region as into a trough. The upper should be high enough in front to allow the freest toe flexion and over the middle of the foot to let the dorsum of the foot raise itself as the toes grasp the sole. The counter should be low to allow free motion at ankle and between astragalus and calcaneum. There should be no "fit," in the usual sense of the word, but yet enough fitness for the particular foot for a loose lacing to prevent slipping at the heel.

Rosenmüller's Fossæ and Their Importance in Relation to the Middle Ear.—F. P. Emerson gives summaries of the clinical histories of eight cases and presents the following conclusions: (1) Pathological amounts of lymphoid tissue are present in Rosenmüller's fossæ in a large number of cases of chronic secretory and suppurative ears. (2) This cannot be detected with certainty by posterior rhinoscopy alone, even where a good view of the vault is obtainable. (3) In every chronic case there should be a routine digital examination. (4) Where much tissue has been found and removed, the process of healing should be watched that no fibrous bands form. (5) It is possible in a large majority of cases to predict the involvement of the ear by the condition of the correspondinf fossa. (6) Results, where after-treatment is followed, are particularly good in removing abnormal sensations, restoring uniform hearing without fluctuations, in the partial or complete relief of tinnitus, and in the prevention of recurring sal-

pingitis. (7) If directions are given to blow one side of the nose at a time and carefully, the affected tube is no more apt to be infected later than its fellow.

New York Medical Journal, April 25, 1908.

Chlorosis Cured by Thyroid Extract.—In connection with a discussion of the general physiology of internal secretions F. K. MacMurrough relates the history of a young woman, single, 22 years of age, occupation bookkeeper, who suffered with symptoms of chlorosis since first menstruation. Fainting spells, heart flutterings, constipation, scanty menstruation, and constant leucorrhea were the more prominent troubles in this case. The blood count was deficient. The treatment consisted of thyroid extract, 3 grains after meals, a daily quart clyster of normal salt solution, Blaud's pills, the practice of deep breathing, and open-air life. All the symptoms yielded which had before been intractable to other modes of treatment.

The Management of Typhoid Fever Without a Nurse.—L. C. Freeny says that the average general practitioner is obliged to do without a trained nurse in three-quarters of his cases. He has adopted the custom of typewriting his directions for a given case and fastening the paper to the wall of the sick room. He does certain things such as giving a bath, etc., once himself to show the family nurse how it should be done. His typhoid directions are as follows: Sponge the patient every three hours when the temperature reaches 102.5° F. or over, unless he is in a sweat. Use a watch to time yourself when sponging, and make it take you at least thirty minutes to complete it. Do not sponge the patient when he is in a sweat, but wait, even if the temperature is high, until the skin is dry and hot, before sponging. Take the temperature every three hours. Give the nourishment every three hours. If you forget the medicine don't forget the nourishment and the temperature. Watch every bowel movement for any sign of blood. Report to me any complaint of pain in the bowels. The nourishment ordered is enough. The patient must not have anything else. Keep quiet in the room and always encourage the patient. Give a warm soapsuds bath every morning at 9 o'clock, and an alcohol rub every evening at 9 o'clock. Never rub the abdomen at all. Write down anything of importance that you may want to ask me; then it will not be forgotten.

Accidents During Anesthesia.—E. R. Zemp enumerates the various accidents which may happen during anesthesia and gives general directions for the conduct of this part of an operation going into great detail. One-eighth grain of morphine and one one hundred and fiftieth grain of atropine are recommended as a routine measure a few minutes before the anesthetic is begun. This quiets the patient, reduces respiratory excitability, steadies the vasomotor system, and lessens the fall of arterial pressure so certain to occur under chloroform. Concerning stertorous breathing, the author says this may be palatine, mucous, or pharyngeal. The first two are not significant, but the third calls for removal of the cone or mask as it is caused by the tongue falling back against the posterior pharyngeal wall, and if not attended to the patient may suddenly suck his tongue tightly down into his throat, thus cutting off his air entirely. An inspiratory "whoop" is always a sign of danger. The author says further that there is no method known to man of administering an anesthetic that is entirely free from danger. Beware of the anesthetist whose peculiar method of administration has banished the hypodermic needle from the operating room and has reduced the mortality from anesthesia to nothing.

Sudden Blindness and Its Various Causes.—M. Buchanan enumerates the causes of sudden blindness, noting that its occurrence in both eyes simultaneously is rare. Such an accident outside of trauma always suggests a systemic origin. Among the most common causes are toxemias, especially uremia, malaria, anemia, and drugs and poisons, as quinine, lead, and alcohol. Uremic amaurosis is most common in the nephritis of scarlatina and pregnancy. Methyl alcohol poisoning (wood alcohol) is becoming more common on account of its cheapness and its substitution in cheap whiskeys and many toilet preparations. In such cases the visual fields, if blindness is not complete, are contracted and show a central absolute scotoma. Quinine in large doses may produce total blindness due to spasm of the vessels diminishing the blood supply and causing a degeneration of the ganglion cells and nerve fibers of the retina and optic nerve. Hysterical blindness is rarely bilateral. Transitory blindness sometimes occurs with brain tumors, especially when the occipital lobe is involved. Complete sudden loss of sight in one eye without external signs of inflammation suggests embolism of the central artery, complete detachment of the retina or an extensive hemorrhage into the vitreous chamber. Thrombosis also of the central vein of the retina causes almost complete loss of sight at the time of occurrence and may ultimately lead to permanent blindness. Transitory forms of monocular blindness may occur, due presumably to vascular spasm. The foregoing are a few of the many points elaborated by the author.

Journal of the American Medical Association, April 25, 1908.

The X-Ray in Leukemia.—A. Stengel and H. K. Pancoast advocate the use of a new method of treating leukemia by the *x*-ray—applying the radiation to the bone marrow instead of to the spleen, as has hitherto been the practice. According to the majority of pathologists, it is the bone marrow that is primarily involved in the lienomedullary or mixed forms, and recent researches have developed evidence that this is true also in lymphatic leukemia. The unsatisfactory results of *x*-ray treatment as hitherto given, with its only 8.7 per cent. of ultimate cures, is noticed, and the probable reason, viz., that the *x*-ray treatment has been directed against a result instead of the cause or seat of the disease, is pointed out. The rapid destruction of lymphoid tissue, such as is apt to follow direct splenic exposures, is, moreover, not always wise or safe, as a toxemia is easily induced thereby, and has even caused death in some cases. Five patients have been treated by the new method with encouraging clinical results. The technique of the treatment is described in detail; the length of exposures, their frequency, the avoidance of any production of toxemia, the points of application, etc., are all discussed. They find that the enlarged spleen is reduced in size, just as it is with direct applications, though more slowly, and the misleading tendency of a comparatively quick symptomatic cure is avoided. The patient's general condition is, on the whole, better from the start with this method, and toxemia can be avoided. The treatment must be systematic; cessation of it for long intervals is to be guarded against, especially in the early stages, and even short interruptions are not advisable until the disease is well under control. The proper time to stop treatment is undecided, but usually not until the conditions are normal, and it is wiser to stop gradually rather than at once. Lymphatic cases respond well to this method, but it is advisable to observe the same precautions in regard to applications to the glands as to the spleen, viz., not to expose them directly to the *x*-rays until considerably reduced in size and the patient's general condition has greatly improved, and then with caution. Exposures are distributed almost all over the body, and the risk of severe dermatitis is, with ordinary care, very slight. The bone pains of splenomedullary leukemia are early relieved by this treatment. The leucocyte count is found by the authors to be of comparatively slight importance, *per se*, but the differential count is one of the important indices to the effect of the treatment.

Hyoscine and Scopolamine Hydrobromide in Refraction Work.—W. Reber gives his experience with hyoscine hydrobromide and scopolamine hydrobromide in refraction work, and more particularly the results of some experimental tests of the effects of these drugs on the pupils and on accommodation, respectively. Of the two salts, that of hyoscine seems to be the most effective, the relative pharmacodynamic power as used in ordinary office work being given by him as somewhere near 59:92. In other words, hyoscine showed itself in these experiments to be approximately 50 per cent. more potent than scopolamine in producing cycloplegia for refraction work. The experiments thus confirmed his opinion formed by clinical observation which had led him to suspect the inferiority of scopolamine. During the last six years Reber has used 1/10 per cent. solution of hyoscine hydrobromate (1/4 grain to the ounce), containing cocaine also in the strength of 1/5 per cent. in something like 2,000 cases of refraction in private practice, without once seeing any pronounced toxemia. In about one case in fifty there was some flushing and quickening of the pulse with slight vertigo, which he attributes to the failure of the patient to press tightly over the canaliculus after the drug was instilled. He has used it as freely in small children as in adults. Customarily he has the solution instilled once or twice the evening before and twice on the morning of the consultation. For office instillation the use of the solution is preceded by one drop of a 2 per cent. cocaine solution, warmed like the hyoscine drops. Two hyoscine instillations are made half an hour apart, and in any time one or two hours after the first instillation the refraction may be satisfactorily tested in the vast majority of cases. Accommodation sufficient for everything but the most exacting near work is generally reestablished by the end of from forty-eight to sixty hours.

Treatment of Chronic Trachoma.—A. E. Prince recommends the use of a 10 per cent. solution of copper sulphate in glycerine, put in the patient's hands with instructions to dilute one drop in twenty drops of water and to use freely on the eye from four to six times as the best home treatment for chronic trachoma. In some cases a weaker solution has been found advisable, but toleration is soon acquired by most patients and some have borne well a strength of one to five. He believes it more efficient than the occasional application of the bluestone crystal. He still finds a few cases, however, in which his former favorite prescription of tannin and mercuric oxide ointment, 1.5 per cent., comes into play, with some sulphate of copper added as an adjuvant. Nitrate of silver is also sometimes useful in addition to other remedies, especially when there is mucopurulent secretion. None, however, is in his opinion so generally useful as the copper and glycerine solution. Of equal importance is the necessity of removing trachomatous material that may prevent the remedy from reaching deeply situated infection. Some have erred in putting too much reliance on the operation and not following it up with a remedy that attacks the disease after it has been exposed. The various complications of trachoma and their treatment are discussed in some detail. Prince finds jequirity a useful drug in pannus due to trachoma, but he uses it commencing with a very weak solution, 0.25 per cent. at the commencement, and uses a fresh solution every day. For the entropion operation he prefers the Anagnastakis method.

Pyelitis from Appendicitis.—Four cases, rather unique in literature, illustrating the connection of acute pyelitis with appendicitis, are reported or referred to by G. L. Hunner. The cases are of special significance because of the obscurity of the symptoms of the antecedent attack of appendicitis, and a dependence on the urinary findings to the exclusion of other diagnostic aids might end in disaster. Two features in these cases besides the abnormal urine suggest themselves as being fairly constant and therefore of possible future diagnostic value; these are bladder disturbance and the early cessation of the microscopical signs of urinary tract disease. These were present in all four cases. The pathology is suggested by the findings in Case 1. The appendix was densely adherent over the pelvic ureter. This would naturally lead to inflammation and obstruction, causing acute hydronephrosis with its chances of kidney infection. Hunner's meeting with four such cases in three years makes him think that they cannot be very rare, and Dr. Edward Ochsner has told him of two similar cases coming under the observation of himself and his brother. Hunner mentions an observation of still another case, probably of this class, which he did not include in his paper because the urinary symptoms were not marked. The importance of early recognition of these cases is obvious. A pyelitis or kidney condition, in itself, is rarely immediately dangerous, but the overlooking of an acute fulminating appendicitis because of dependence on the urinary examination might cost the patient his life.

The Lancet, April 18, 1908.

A Cavity of the Lung Successfully Treated with Ozone.—G. Stokes reports the case of a man who had pneumonia with pleurisy followed by empyema for which portions of ribs were resected in front and behind. The posterior wound healed satisfactorily but the anterior did not. The discharge became offensive and putrid and he became septic. He was treated with a vaccine on the Wright principle and in due time a small piece of lung tissue came away with a subsidence of the sepsis. There was left a lung cavity and sinus extending over six inches from the chest wall and communicating with the bronchi. This cavity was treated with ozone gas injected under pressure, and after a course of treatment carried out on thirty different days extending over a period of seven weeks the patient was cured. The author says that the bacteriological changes which took place confirm the following statements: (1) Microorganisms that are under healthy conditions good and useful will under unhealthy conditions become hostile; (2) that unhealthy microorganisms require unwholesome matter for their nourishment; (3) that ozone and oxygen act by so changing and purifying the discharges that unhealthy microorganisms, being deprived of the matter necessary for their existence, decrease and finally disappear; and (4) that oxygen and ozone have this effect on every microorganism he has ever been able to discover in wounds or suppurating surfaces except the staphylococci, which under these conditions increase in number and often in size. These conclusions are the result of observations and microscopical examinations of the pus from some 500 cases treated with oxygen and ozone. In the foregoing case, before commencing the treatment a specimen of pus was taken from the wound and a culture was made from it for microscopical examination. This was repeated at intervals during the treatment. The microphotographs taken of the slides that were prepared show steady decrease and final disappearance of those microorganisms that are hostile to healing, and a steady increase of the staphylococci which under the influence of ozone and oxygen always increase in number and often in size as the healing process goes on.

Possible Relationship Between the Diphtheritic Affection of Man and Those of the Lower Animals.—L. W. Sambon says that in diphtheria as in plague we are confronted by the difficulties of a complex and intricate epidemiology. As in plague, so in diphtheria, a number of different animals seem to play a more or less important part in fostering and spreading the disease. But in diphtheria, as in plague, one particular kind of animal seems more especially concerned in the wider spread of the disease. In plague the rat, owing to its wide distribution, its great numerical prevalence, its close association with man, and, above all, its migratorial habits, is the true cause of the great pandemics which at various intervals desolate the world. In diphtheria probably a similar rôle is played by the pigeon. The author refers to various classes of animals which suffer from diphtheria. Among these are turkeys, peacocks, guinea fowl, domestic and water fowl, and parrots. He quotes from various authorities as to its occurrence in horses, cattle, sheep, rabbits, mice, dogs, etc. The history of epidemics of the disease seem to prove conclusively the transmissibility of it from man to animals and vice versa. The contagiousness of the disease presents certain limitations. It is frequently confined to a certain locality, and unlike other contagious diseases creeps slowly from place to place. Its conveyance by means of milk and eggs would explain the great frequency of the disease in young children because their food consists almost entirely of these two articles frequently administered to them either in the raw condition or almost raw. It is probably by means of these foodstuffs that the disease is brought into towns, although, of course, it may also be introduced by infected human subjects or by infected animals, especially birds such as the ring dove and the house sparrow. Within recent years the ring dove has become quite common in all the parks and squares of large cities. It may be seen picking the seeds that strew the pavement of cab-ranks. It is quite conceivable that horses and sparrows may contract the disease from these pigeons. It is likewise conceivable that the cat, a natural enemy of the sparrow, may contract the disease from this bird, which is likely to fall an easy prey when paralyzed by the disease. The rôle of the cat with regard to diphtheria appears to be of great importance. This animal after prowling in field and gutter has access to the sanctum of the bedchamber, sleeps on the very bed, is fondled and kissed by the children, especially by the female children. Since 1800, when Noah Webster drew attention to the cat as a factor in the epidemiology of diphtheria, this animal has been noticed to suffer simultaneously with man in almost every outbreak of the disease.

British Medical Journal, April 18, 1908.

Unusual Abnormality of the Finger Tips.—B. Malcolm reports the case of a man in whom there was complete absence of the nails on the thumb, forefinger, middle finger, and radial half of the ring finger. The nail was complete on the little finger, and there was half a nail on the ulnar side of the ring finger. The feet showed a corresponding condition. Naturally the absence of nails gave a peculiar appearance to the fingers and toes. The ends were rounded in every direction, not unlike the appearance of an amputation stump. There was no thickening of the skin on the dorsal aspect of the fingers or toes. The utility of the fingers was very little impaired. A pin was picked up from the floor with ease. The only thing that bothered the patient was the opening of a small pocket-knife; he had to use a coin to open it. The following account with regard to the man's family history, which covers four generations, was obtained. His maternal grandmother had the same condition, and his mother, and two of her brothers and one of her sisters. In the third generation it exists in all the patient's brothers and sisters, and among his cousins on the mother's side. The patient himself, aged 27, has had two children, of whom one, now dead, had the condition, and the other is free from it. It is obvious, therefore, that the abnormality was inherited and is being transmitted to the fourth generation. It will be observed that the defect precisely corresponds to the finger distribution of the median nerve, which supplies the extremities of three and a half outer fingers, and which seems otherwise perfectly normal. The author has not been able to find any similar case in literature.

Hypersensitiveness to Antidiphtherial Serum.—R. Waterhouse reports his own personal experience with the antistreptococcus serum as well as that used against diphtheria. As a result of an injury to the thumb, which became infected, a swelling of the arms and axillary glands with severe constitutional symptoms resulted and antistreptococcus serum was injected with immediately happy results. Eighteen months later a diphtheritic infection ensued, for which antitoxin was given, and in two hours a most distressing urticaria set in, with pain behind the sternum, palpitation, and faintness, but no vomiting. The antitoxin had been injected in the left arm. These symptoms passed off in two hours, and the next day the author felt all right. Four years after the throat became infected with a membranous deposit, probably diphtheritic. Antitoxin was given, this time in the right flank, but again in almost two hours the same urticarial symptom followed, with, in addition, vomiting and throbbing in the head. The interest of these two attacks consists in the short interval between the injection and the onset of symptoms (not more than two hours on either occasion), in the intensity and short duration of the symptoms, in the striking similarity between the attacks as regards time of onset, symptoms, and duration (though the serums used were from different firms and so probably from different horses), and in the fact that on two previous occasions horse serum had been administered to the author without ill effects.

Primary Pneumococcic Peritonitis.—A. Cuff gives the histories of five patients, all of whom came to operation and three of whom died. Localized pneumococcic disease otherwise than in the lungs is more common in children, and a review of the literature suggests that it is rare in adults, though four of the author's cases were adults. His deductions from his own personal experience are: That an acute diffuse or localized peritonitis may be the sole symptom of a pneumococcic infection; that such cases possibly form a considerable proportion of those anomalous cases of peritonitis without visible lesion of any of the abdominal viscera; sudden onset after previous freedom from abdominal trouble, together with the frequent accompaniment of diarrhea, and signs of early systemic poisoning, may perhaps serve to assist in differentiating them from peritonitis caused by other infection; that they may be followed by pneumococcic lesions in other organs of the body; that their prognosis is extremely grave.

Rectal Temperature after Muscular Exercise.—In a series of tables M. Flack presents the results of his observations, which show that the increase in body temperature during hard muscular work is very great and comes on quickly. Thus, a man showed, after a 220-yards dash, a rectal temperature of 100.85° F. in half a minute after the dash was over. Another man showed in one minute after finishing a mile race 102.6°. It is well known, says the author, that many factors, such as food, age, sex, race, external temperature, besides muscular work, are held to play a part in determining the body temperature. It would appear, however, that muscular work is one of the most important. Indeed, Tigerstedt expresses the opinion that, allowing for modification by food and the external temperature, the diurnal variation observed in man is due to a difference in metabolic activity. If this were so we should expect a reversal of the variation in night workers. The observations on this point are somewhat discordant. Tigerstedt thinks this may be due to the difficulty of sleeping during the day owing to the lack of quietude, and perhaps also to the imperfect exclusion of daylight, factors which must certainly alter the quality of the sleep obtained. Galbraith and Sutherland Simpson have shown that such a reversal can be obtained in apes, and exists in night flying birds. Osborne, too, has recently contributed some interesting observations made upon himself during a voyage from Australia to England, the evening maximum of the diurnal variation taking place rather in regard to local time than to that of the starting place (Melbourne). Although his figures do not disprove the existence of a body periodicity, they tend to show the importance of muscular activity in determining the maximum of the diurnal variation.

Berliner klinische Wochenschrift, March 30 and April 13, 1908.

The Activity of Peptic Digestion.—Gross says that most of the methods of pepsin determination in gastric contents are inaccurate, including the Mett capillary tube method. Volhard's method is too complicated for practical application, and Jacoby's ricin method while simple is open to the objection that ricin is not always uniform in composition and is relatively expensive. He himself uses as test substance purified casein, of which one gram is dissolved in a liter of water by the aid of 16 c.c. of 25 per cent. HCl (sp. g. 1.124), heating on a water bath. Into each of a series of test tubes is placed 10 c.c. of this .1 per cent. solution warmed to 39° to 40° C., together with graduated amounts of the gastric contents to be tested. After fifteen minutes in the thermostat a few drops of concentrated sodium acetate solution are added to each tube, the result being the precipitation of the undigested casein. In this way the minimum amount of gastric contents sufficing to digest all the casein in fifteen minutes may be recognized. The unit of digestive power is represented by the capacity to digest 10 c.c. of the casein solution in fifteen minutes so completely that no precipitate is caused by the addition of sodium acetate. In healthy individuals 0.02 to 0.03 c.c. of gastric contents after a meal of three Albert biscuit taken dry and expressed in three-quarters of an hour suffice to cause complete digestion, that is, 1 c.c. of gastric juice has a peptic power of from thirty to fifty units. By means of tests with this method the author reaches the conclusion that Schütz-Borissow's law that the intensity of peptic digestion is proportional to the square root of the time and amount of ferment is unfounded, and that the digestive activity is directly proportional to the time and amount.

A New Diagnostic Phenomenon in Strictures of the Esophagus.—Rewidzoff says that of the two murmurs that may be heard on auscultation of the esophagus, while the patient swallows some water, the first has no diagnostic value, the second, produced by the entrance of food into the stomach, may be delayed in cases of stricture of the esophagus. Often, however, it is heard in its normal time of from six to eight seconds after the first sound, though a stricture is present. If the patient is asked to repeat the act of swallowing without taking any more water and without swallowing his own saliva, the second sound may be heard again and again in cases of partial obstruction of the esophagus by a stricture. The explanation of this phenomenon is found in the fact that the swallowed liquid does not enter the stomach at the first act of swallowing, because of the obstruction caused by the narrowing of the lumen; the succeeding sham acts of swallowing excite further peristalsis of the esophagus and the entrance of more liquid into the stomach, which results in the characteristic murmur. This phenomenon first observed by the author he has named the "residual sound"; its appearance speaks for the existence of a stricture quite independent of the time in which the second esophageal sound is heard; if repeated, the number of repetitions gives an idea of the size of the esophageal dilatation existing above the stricture and the degree of obstruction.

Münchener medizinische Wochenschrift, March 31 and April 14, 1908.

The Treatment of Cardiospasm.—Geissler describes an instrument designed for the dilatation of spasmodic strictures of the cardia, the use of which he considers has advantages over any of the methods commonly employed. The number of these is very large, but the simplest is by means of the introduction of a soft tube having near its end an inflatable balloon. This is to be passed into the cardia and the balloon is then distended by insufflating air. In the instruments as previously designed this bag is of very elastic rubber and tends to bulge into the stomach without exerting much effect on the stricture, but the author has devised a method of construction which causes the bag to maintain its cylindrical form, thus ensuring the maximum of effect at the site of the spasm. Water may be used instead of air for the purpose of distention. The instrument has been found very successful in practice.

Complications After Operations on the Stomach.—Stieda says that the commonest complications after stomach operations are peritonitis, secondary hemorrhage, and gastric distention through atony. To this number he adds another which is rare but which he has observed in three cases. It consists in persistent vomiting due to an extraordinary increase in local reflex excitability. The vomiting is distinguished from that of atony through its being small in amount and frequently repeated, while the stomach is practically empty, and in the absence of any evidence of peritonitis. In one of the author's cases death followed in spite of relaparotomy and jejunostomy. The diagnosis is important since the treatment consists of the administration of narcotics, especially atropine, and if rectal alimentation proves insufficient, in performing jejunostomy.

Accidental Heart Murmurs in Pregnancy.—Link examined 330 pregnant women in reference to this point. Forty-one of them, or 14 per cent., showed the pres-

ence of an accidental heart murmur, systolic in time, best heard in the second left interspace, soft blowing in quality. There was no accentuation of the second pulmonary sound, nor any change in the heart sounds at the apex. After delivery the murmur disappeared in twenty-six cases, twelve patients were not examined, and in three cases the murmur persisted, one of them in a markedly chlorotic patient. Link explains the origin of this murmur by the fact that the heart is crowded upward and forward, which results in slight kinking of the pulmonary artery; its absence in some cases of pregnancy he explains by the individual differences in the size of the gravid uterus, in the condition of the abdominal walls, and in the stature of the patients. Most of the patients examined by him were small in stature. The differential diagnosis between this functional murmur and the murmur of heart disease was made somewhat difficult by the displacement of the heart and the increase in the size of the mammary glands. The maximum intensity of the murmur at the pulmonic area and the absence of accentuation of the second pulmonic sound, however, were decisive and an erroneous diagnosis was made in only two cases.

A Phosphatometer, Phosphoric Acid in the Urine, and Phosphaturia.—Friedmann describes a simple apparatus of his own invention for the quantitative estimation of the phosphates in the urine. It consists of a glass tube in which a measured quantity of urine may be mixed with magnesia mixture. The phosphates are precipitated in the form of ammoniomagnesium phosphates, and the reading taken after twenty-four hours is compared with an experimentally constructed table, which gives the phosphate content in grams per liter. The normal amount of phosphoric acid he has found to average 2.6 grams in the twenty-four hours, the figures for one hundred estimations varying from 1.5 to 3.6 grams. Under the term "phosphaturia" Friedmann understands, not the increased precipitation of phosphates in the urine, such as is noticed in diminished acidity of the urine, in sexual neurasthenia, etc., but actual quantitative increase in the excretion of phosphates in the twenty-four hours. He gives the data in a case observed by him, which could be classified, according to the nomenclature of Teissier, as phosphatic diabetes. The patient's urine contained sugar and an excess of phosphates; the former disappeared on a semi-vegetarian diet, the latter persisted; the nitrogen metabolism was markedly diminished, though crystals of uric acid were deposited in abundance. The author has further noted phosphaturia in chronic affections of the bones, in chlorosis, in oxaluria, and in some cases of so-called uric-acid diathesis. On the other hand, the excretion of phosphates was diminished in pregnancy, in pernicious anemia, in leukemia, in acute yellow atrophy, and in cirrhosis of the liver. In acute and chronic parenchymatous nephritis, in uremia, and in the nephritis due to congestion a normal amount of phosphates was excreted; in cases of contracted kidney, on the other hand, the phosphates were much diminished.

Deutsche medizinische Wochenschrift, March 26 and April 2, 1908.

Short Exposures in Roentgen Ray Work.—Levy-Dorn in discussing the subjects of Roentgen ray work says that for many purposes, especially for the production of pictures of moving organs, such as the thoracic viscera, it is of the greatest importance to be able to secure adequate exposures in the shortest possible time. Various devices and procedures have been recommended with this end in view, such as special coils, intensifying diaphragms, and the use of exceedingly rapid plates. By aid of such methods Rosenthal has succeeded in securing adequately exposed plates of the thorax in two seconds and of the hip in six. Levy-Dorn is of the opinion, however, that the employment of ultra-rapid plates and of intensifying diaphragms is not to be recommended for the ordinary worker on account of the tendency to produce fogged or indistinct negatives. He then describes a form of apparatus by means of which it is possible to obtain good chest pictures in five seconds and hip pictures in fifteen seconds, with the tube at a distance of from fifty to sixty cm.

An Unusual Case of Castration.—Stieda describes a case of this sort presenting several remarkable features. The patient was a man of thirty-six years, who lost his testicles at the age of fifteen years as the result of an act of barbarity perpetrated by three men. Two of these held him while the third squeezed the testicles between his fingers until they were entirely crushed, the procedure lasting an hour. When the swelling and pain caused had subsided he was no longer able to feel any trace of the testicles and the genitals did not develop further. No beard appeared, the voice did not change, but at his nineteenth year he began to grow rapidly, and whereas he had formerly been small and puny he now is 175 cm. in height and is correspondingly broad and heavy. His sexual ability is good and he has satisfactory erections, which permit him to have coitus normally, except that the amount of ejaculated fluid is small. He married at the age of thirty, but has no children. The larynx is small and there is hypertrophy of the mammary glands. The pubic hair resembles the female type in its arrangement. A characteristic feature is the length of the bones of the extremities, which continue to grow longer in castrated individuals than normally owing to the late ossification of the epiphyses.

Cervical Ribs and Trauma.—Franck says that up to 1894 there were only eleven cases on record in which the diagnosis of cervical rib was made during life though the anomaly had been discovered after death in ninety-five cases. Since that time, however, the recognition of this condition has been more frequently reported, and in 1898 twelve cases treated by operation were described by Fick. Kuester has pointed out that accidents sometimes lead to the first occurrence of symptoms due to the deformity, a view shared by Franck. The fact that the patient may first have his attention called to the presence of the rib after some accidental trauma has a bearing on the subject of accident insurance, and he describes a case in point. The patient while carrying two pails of milk by the aid of a yoke was injured about the left shoulder through slipping of the yoke. As a result there were pain, paresthesia, and atrophy in the left arm, and Roentgen ray examination demonstrated the presence of a cervical rib. As the symptoms did not subside the accessory bone was removed by operation with almost, but not quite, complete relief. The patient claimed accident indemnity, which was accorded on the ground that if it had not been for the trauma she would not have suffered from the existence of the abnormality.

Resection of the Pancreas.—Ehrhardt says that gastric and intestinal surgery has now reached such a point of development that pancreatic operations are possible with good chances of success. So far about forty or fifty cases are on record in which larger or smaller portions of the gland were removed for primary or secondary new growths. The inaccessible position of the organ and its close relationship to numerous large vessels, such as the portal vein, vena cava, superior mesenteric vessels, and the pancreatico-duodenal vessels render removal of portions of a distorted and diseased gland exceedingly difficult. While the danger of diabetes or of disorders in fat digestion is not very great after these operations, a real peril is formed by the changes taking place in the cut surface through the action of the secretions of the gland itself. The author describes two cases in which he successfully removed considerable portions of the pancreas for malignant involvement secondary to pyloric carcinoma, the patient surviving the operation five months in the one case and over one and a half years in the other.

French and Italian Journals.

Adenomata and Cysts of the Parotid.—P. Lecene says that adenomata of the parotid are little known. They resemble the mixed tumors of the gland. They are encapsulated, and can be enucleated, and are adherent to the glandular tissue. They generally contain cystic cavities lined with cubical epithelium. They are of small size, and contain several varieties of tissue—muscular, cartilaginous, mucous, and embryonal connective tissue. They are slow in development and do not give pain, but should be removed on account of their tendency to malignant degeneration. The author has made examinations of four cases of cyst of the parotid, and finds that the tissues are not typical of the gland, but show the cysts to be congenital branchiogenic cysts. The treatment is removal.—*Revue de Chirurgie,* January, 1908.

Diagnosis of Acute Miliary Tuberculosis.—A. Ceconi says that in acute miliary tuberculosis it is almost impossible to aid diagnosis by demonstrating the presence of the bacilli in the blood. Serodiagnosis and culture experiments also fail to aid us. But there are several symptoms that are of diagnostic value in these cases. They are dyspnea, polipnea, paroxysmal cough, and cyanosis, combined with frequency of the pulse. In abdominal typhoid, we should have digestive symptoms, swelling of the spleen, and the peculiar course of the fever to differentiate the disease. The pulse in tuberculosis will be small and very soft, while lacking dicrotism. The arterial pressure is diminished, and the rapidity of the pulse is out of proportion to the rise of temperature.—*Il Policlinico,* November 19, 1907.

Book Reviews.

THE INTERNATIONAL MEDICAL ANNUAL. A Yearbook of Treatment and Practitioners' Index. By Thirty-three Department Editors. Twenty-sixth Year. New York: E. B. Treat & Company, 1908.

THIS excellent work, by a process of national selection, has now become the recognized yearbook to which one turns for a record of all that is new in medical science. The plan of the work remains the same as in previous editions. The first part is a Dictionary of Materia Medica and Therapeutics, wherein are noted, in alphabetical order, all the new drugs of the year, and the new uses to which some of the older drugs have been put. The second and largest part is a Dictionary of Treatment, including a review of medical and surgical progress. After a cursory review of the progress during the year in the several departments and specialties, the various diseases, medical and surgical, are taken up in alphabetical order, and whatever is new in relation to them—especially their treatment—is noted. In the third section, the advances in sanitary science are recorded.

THE PRODUCTION AND HANDLING OF CLEAN MILK. By KENELM WINSLOW, M.D., M.D.V., B.A.S. (Harv.). Formerly Instructor in Bussey Agricultural Institute and Assistant Professor in the Veterinary School of Harvard University. Author of a Textbook on Veterinary Materia Medica and Therapeutics, Chairman of the Committee on Milk of the Washington State Medical Association, etc. New York: William R. Jenkins Co., 1907.

THIS is a very well written, simple, and practical guide, of use to the health officer in teaching him what to demand of the milk producer, and to the dairyman in showing him how he can with slight additional expense meet the demands of the sanitarian. It treats of the significance of germs in milk, of the composition of milk and cream, of the cow and her care, of milking, and of the handling and distribution of milk, and of milk infection. An interesting and practical chapter is one on the cost of producing and distributing clean milk. In this the author holds the somewhat novel view that the responsibility for dirty milk rests mainly and finally upon the consumer who is unwilling to meet the increased cost of producing clean milk. "When the public is sufficiently aroused to the evils of consuming unclean milk," he says, "and evinces willingness to pay for clean milk, there will be no difficulty about production." He strongly opposes pasteurization, but apparently confuses it with sterilization, or at least has a very hazy notion of its effect upon the nutritive quality of milk. Nevertheless, he regards it as necessary in the case of dirty milk. The illustrations are numerous and good. The work is to be welcomed by all who believe that the final solution of the milk problem lies in the education of the farmer and of the handler of milk.

MEDICAL DIAGNOSIS. A Manual for Students and Practitioners. By CHARLES LYMAN GREENE, M.D., Professor of the Theory and Practice of Medicine in the University of Minnesota; Attending Physician, St. Luke's Hospital, the City Hospital, and the St. Paul Free Dispensary, etc. Second Edition. Revised, with 7 Colored Plates and 241 Illustrations. Philadelphia: P. Blakiston's Sons & Co., 1907.

THE good opinion which we expressed of this book when it appeared in the spring of last year has been justified by the reception accorded it by the profession. The call for a second edition within seven months of the date of publication is an evidence that the work has met a want. There are naturally few changes called for in so short a period, and practically the only addition of importance is a description of the opsonic technique. This is illustrated with some excellent pictures. The word opsonin is said to come from the Greek word *orhsopo*, which is rather the worst of the many weird etymological efforts in relation to the word that we have yet seen. In general, however, the book is quite free from typographical errors.

AUSCULTATION AND PERCUSSION; Together with the Other Methods of Physical Examination of the Chest. By SAMUEL GEE, M.D., Fellow of the Royal College of Physicians, Honorary Physician to H. R. H. the Prince of Wales, and Consulting Physician to Saint Bartholomew's Hospital. Fifth Edition. London: Henry Frowde, Oxford University Press; Hodder and Stoughton, 1907.

IN the limited sense in which the author has treated his subject, this excellent little book is both complete, and, at the same time, has the advantage of brevity. Part First is given over to a careful record of the terms used in physical examination of the chest, and a clear and concise description of these terms. The author has very properly followed in all essential particulars the classification and terminology of Laenec. Therefore, there is a striking simplicity of definition and an attempt at return to a standard nomenclature, which is edifying and refreshing. Many points in the physical diagnosis of the chest, which the practitioner is apt to forget, are forcibly brought out, and while, from the nature of the subject, there can be little or nothing really new, one can only with advantage and profit spend the few hours necessary to read over this author's excellent review of the subject.

Part Two is taken up with a practical application of the doctrines and methods which the author has exploited in Part One. This division of the work is quite as clear and concise as the former. It is questionable whether the author in such a work has done wisely to omit a brief discussion at least of some of the newer methods of physical diagnosis of the chest, which have in recent years been made possible by the Röntgen rays. The book is well indexed, and is published in a most convenient form and size.

MATERNITY. By HENRY D. FRY, M.D., Sc.D., Professor of Obstetrics Medical Department of the Georgetown University; Obstetrician-in-Chief Columbia Lying-in and Georgetown University Hospitals; Gynecologist to Garfield Memorial Hospital, etc. New York and Washington: The Neale Publishing Company, 1907.

ON the wrapper surrounding the volume we are informed that this is "a book for the lay reader, the medical student, and the trained nurse." For the medical student it is certainly far too elementary to have any value at all. As a book to be placed in the hands of the prospective mother, it may possibly serve some purpose in supplying the information which she should have. But even for this class of reader there is much that is of no value; for instance, the references to pregnancy and labor in the Book of Genesis, the statement that cesarean section was practised by the Israelites, and that women in labor were "assisted by being hung head downwards and shaken, then rolled upon the ground and trampled under the feet * * * finally the infant was destroyed, cut up, and extracted by instruments." This may be interesting, but it is hardly healthy reading for a pregnant woman; indeed, the author says on page 95 "harmful to a degree are the visits of officious friends, who terrify her by the recital of horrible complications and difficult labors and the birth of monstrosities." The book needs considerable pruning before we would care to recommend it to any expectant mother.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of the Theory and Practice of Medicine, and of Clinical Medicine, Medico-Chirurgical College, Philadelphia. Eighth Revised Edition. Philadelphia and London: W. B. Saunders Company, 1907.

THE distinguishing feature of Anders' Practice, and the one which has made it essential to any complete medical library, is the attention given to the Symptomatology and Diagnosis. The sections devoted to these subjects are elaborate and of peculiar value, and even in the first edition stamped the work as one of service, despite the slight tendency to therapeutic nihilism, which was the fashion in medical teaching a decade ago. This fault has been gradually corrected in the successive editions, and now the work may be recommended as a safe therapeutic, as well as diagnostic guide. A number of new subjects are treated of in this edition, and the important section on animal parasitic diseases has been thoroughly revised, a number of the articles having been entirely rewritten.

VERHANDLUNGEN DER DEUTSCHEN LARYNGOLOGISCHEN GESELLSCHAFT auf dem II. Versammlung Sep. 15-18, 1907. Herausgegeben von Dr. Med. Georg Avellis. Berlin: Curt Kabitsch, 1908.

THIS volume of transactions of the recently organized national society of German rhinologists and laryngologists opens with an obituary notice of the late Prof. Moritz Schmitz, who was its president at its inaugural meeting, and did much to give the organization a flourishing start. Then follow the usual executive business sections, and lastly come 34 papers on scientific topics. The book closes with the usual lists of members, etc. As most of the papers have appeared in abstract in the current journals of this special branch of medicine, and some of them have been published in full, no special comment is here needed. As especially noteworthy, we may mention the following: Kuttner, "Laryngeal Tuberculosis and Pregnancy"; Heymann, "Division of the Nasal Accessory Sinuses"; Saenger, "Asthma Therapy"; Hoffman, "Osteoplastic Operations in Chronic Frontal Sinus Disease"; Rosenberg, "Cold Abscess of the Larynx"; Blumenfeld, "Adenoid Growths and Intrathoracic Glands," and Hajek, "Accidents of Antral Puncture."

Society Reports.

TENNESSEE STATE MEDICAL ASSOCIATION.

Seventy-fifth Annual meeting, held at Knoxville, April 14, 15, and 16, 1908.

THE PRESIDENT, DR. A. B. COOKE OF NASHVILLE, IN THE CHAIR.

THE Association met in the Circuit Court Room of the Court House.

Addresses of welcome were delivered by Hon. John M. Brooks, Mayor of Knoxville, on behalf of the city, and by Dr. H. H. McCampbell, on behalf of the Knox County Medical Society, which were responded to by Dr. W. D. Haggard of Nashville.

Medical Organization; Its Purposes and Possibilities.—PRESIDENT COOKE, in selecting this subject for his address, pointed out that the purposes of the Association were to federate and bring into one compact organization the entire medical profession of the State and to unite with similar associations in other States to form the American Medical Association, with a view to the extension of medical knowledge and the advancement of medical science, to the elevation of the standard of medical education and to the enactment and enforcement of just medical laws, to the promotion of friendly intercourse among physicians, and to the guarding and fostering of their medical interests, and to the enlightenment and direction of public opinion in regard to the great problems of State medicine, so that the profession shall become more capable and honorable within itself and more useful to the public in the prevention and cure of disease and in prolonging and adding comfort to life. As to the possibilities of medical organization, the present scheme of reorganization was only six years old, and yet in that short time the advantages which had been realized were so positive and definite that the promise for the future seemed bright. To those who believed in the soundness and equity of a representative form of government, the plan whereby the county society was made the unit of organization must commend itself as both wise and just. The great underlying purpose of all medical organizations was to reach the individual physician, to cause him to realize that he had other responsibilities and duties than those which pertained to his immediate clientele, to broaden his mental vision, to awaken him to the fact that association with his fellows would enable him to mold public opinion and wield an influence in the affairs of men which were not possible in any other way. Systematic effort to reach the individual physician and induce him to affiliate with his local society, and in the possibilities embraced in such affiliation, he found one of the strongest defences of the present scheme of organization.

Laceration of the Perineum.—Dr. C. E. RISTINE of Knoxville read a paper on this subject, in which he described the basic principle of a new operation for secondary repair of complete laceration of the perineum.

Ophthalmia Neonatorum.—Dr. HILLIARD WOOD of Nashville referred to the prevalence of ophthalmia neonatorum before the introduction of Credé's prophylaxis and its reduction by the judicious use of a solution of silver. The percentage of blind in the Tennessee School for the Blind from this disease was referred to, and the author emphasized the necessity for a more determined effort to prevent blindness from this cause.

Dr. M. M. CULLOM of Nashville said the method of using solutions of silver was simple, and could be employed by any practitioner, and the use of the silver salts, whether nitrate of silver or the newer salts, should be adopted, in his judgment, as a routine measure.

Dr. LOUIS LEROY of Nashville said that when the disease was once established there was infiltration of the deeper layers of the cornea by the gonococcus. When the child was just born, however, there was no infiltration of the corneal tissues. The gonococci were present on the surface, and for that reason nitrate of silver would kill them as effectively as any of the other newer preparations.

Dr. S. S. CROCKETT of Nashville had not been able to determine always when there was a purulent infection of the eyes, and, while he had been practising many years, and had done considerable obstetric work, he had never seen a case of ophthalmia neonatorum. He doubted very much whether every practitioner doing obstetric work could be induced to use nitrate of silver in the eyes of every baby just born. He doubted its practicability.

Dr. JERE L. CROOK of Jackson thought the members should place themselves on record as favoring, advocating, and personally practising the instillation of a 2 per cent. solution of nitrate of silver, as recommended by Credé, in every case.

Dr. A. F. RICHARDS of Sparta agreed with Dr. Leroy as to the preference for nitrate of silver solution to the other salts.

Dr. CHARLES P. MCNABB of Knoxville believed that if practitioners would wash the eyelids and eyelashes of newborn babies with sterile water there would be no, or less, ophthalmia neonatorum. A 2 per cent. solution of nitrate of silver did not, or would not, kill pyogenic bacteria.

Dr. G. E. VAUGHAN of Clarksville spoke of regulating the practice of midwives, saying they were the cause of most of the cases of ophthalmia neonatorum.

Dr. G. M. BURDETTE of Lenoir City had not had more than one case of ophthalmia neonatorum during a long practice. This case was treated with nitrate of silver, but it took six weeks to get rid of the infection. He used sterile water invariably in washing the eyes of babies. He could not support the indiscriminate use of nitrate of silver solution.

Obstruction of the Ureter.—Dr. M. C. MCGANNON of Nashville described an interesting case of obstruction of the ureter, and an operation which he had performed for its relief.

Treatment of the Stump of the Appendix.—Dr B. MERRILL RICKETTS of Cincinnati, by invitation, said that much had been said and written about dealing with the stump of the appendix without any very definite conclusions being drawn. The dangers resulting from imperfect technic may be great. He sent letters of inquiry to surgeons of more or less experience, requesting a description of the method used by each. Sixty-four replies were received, representing 80,251 operations, among which about sixty cases of hemorrhage from one or more branches of the vessels of the appendix were reported. Twenty lantern slides were presented to illustrate the various methods of ligating the stump. His conclusions were that simple ligature with silk was the quickest and safest method.

Practical Deductions in the Diagnosis and Treatment of Appendical Infections.—Dr. W. D. HAGGARD of Nashville summarized by saying (1) that the treatment of appendicitis should be surgical operation in all well-marked cases as soon as the diagnosis was made within the first twenty-four or forty-eight hours, if possible. (2) Immediate operation in cases which had apparently been doing well, but suddenly had a chill or a drop in temperature, with rise of pulse. If vomiting returned after having stopped, or if inflammatory pain reappeared after the original seizure had abated, or from any cause perforation or gangrene was suspected. (3) Moderately severe cases seen on the third, fourth or fifth day, who had not had the benefit of early operation, and especially if there was any special contraindication to operation, were given their best chance by the Ochsner method. (4) Cases seen when the process was distinctly abating were treated in the above manner, and operation deferred until the attack had completely subsided. (5) Cases with

well-defined abscesses seen on or about the end of the first week could often be watched a few days if there was any opportunity of the abscess becoming adherent to the abdominal wall. If this occurred, adhesions were quite competent at the end of the tenth day, and evacuation should be practised, but the appendix left alone, unless it was easily seen, and very accessible in the abscess cavity. (6) In general peritonitis a short operation with quick removal of the appendix, no irrigation, a large glass tube in the pelvis above the pubes, the patient in the Fowler position, and the bloodwashing, continuous enema of salt solution, was the best treatment. Where the abscess was not adherent to the abdominal wall, the entire field should be walled off with gauze before opening and sponging it dry. Irrigation should not be used. (7) Cases after one attack were safer with operation in the interval than to wait for another attack. (8) If the interval had been allowed to elapse without operation, and the second or third attack should become inaugurated, operation in the first few hours of the attack, while the infection was still confined with the lumen of the appendix, was about as safely treated with immediate operation as with operation in the interval. Moreover, all of the dangerous possibilities of that attack were cut short.

Colic.—Dr. W. J. Breeding of Ravenscroft, in a paper on this subject said, among other things, that if the profession would only realize that at least ninety pathological causes of colic requiring only medical treatment might exist within the abdominal cavity, and that over one hundred serious surgical causes might find expression in colic, physicians would certainly deliberate long before obscuring symptoms by an early resort to the preparations of opium.

Dr. George R. West of Chattanooga said he followed the Wyeth method of treating the stump of the appendix. He narrated a case in which jaundice occurred several times as the result of a postcecal abscess due to a long-standing appendicitis in which the appendix was adherent.

Dr. Louis Leroy referred to colics of nervous origin and to those associated with hysteria, classed vaguely with the ovarian colics. He also mentioned colics due to the habitual use of morphine.

Dr. Jere L. Crook spoke of the simplicity of the Dawbarn method in treating the stump of the appendix.

Dr. A. G. Kyle said he resorted to the Dawbarn method whenever he had a soft appendix to deal with, as it was so simple.

Dr. M. C. McGannon said that tabes dorsalis produced pain about the abdomen which might be mistaken for gall-bladder or appendiceal trouble. Jaundice was very rare as a symptom of appendicitis. There must be some other condition than appendicitis to produce jaundice.

Salicylate of Mercury in the Treatment of Syphilis.—Dr. J. W. Handly of Nashville described the use of intramuscular injections of salicylate of mercury in the treatment of this disease, and said it was applicable in all stages, the intervals being governed by the results obtained. In deep ocular lesions, as retinitis, choroiditis, iritis, he found the deep injections especially effective, particularly when combined with the iodides. To summarize, intramuscular injections were best for the following reasons: (1) Accuracy of dosage. (2) Better control of patient. (3) Secrecy of treatment. (4) No gastrointestinal disturbance. (5) Little tendency to salivation which could be quickly controlled. (6) Patient could not give remedies to other patients, thereby cutting out the other fee of the physician. (7) Patient was not forced to take three doses a day, but one injection every seven to ten days. (8) No smearing over the body with a filthy ointment, a tell-tale bearer to those around him. (9) The greatest good to the patient with the smallest amount of trouble.

Dr. Jere L. Crook had tried this treatment in three cases, in one of which the result obtained was fine. It was very important to get a good syringe for giving the injections.

Dr. Louis Leroy said mercurial injections in cases of syphilis were the surest and infinitely the most rapid method at our command. They did not disturb digestion, and a good digestive system was one of the best assets that a man had in overcoming syphilitic infection.

Snoring, Mouth-breathing.—Dr. G. E. Vaughan of Clarksville said the most frequent cause of mouth-breathing in a child was adenoids and enlarged tonsils. The next was hypertrophic rhinitis, and he called particular attention to this, as it was frequently neglected. The enlarged turbinate was considered frequently to be the result of adenoids and enlarged tonsils, and yet it did not always disappear after their removal. So he was constrained to believe that the enlarged turbinate, adenoids, and tonsils were all the result of some condition, but not always dependent on each other. A grievous mistake was made by not following up cases on which operations had been done for adenoids and tonsils, and seeing to it that nasal obstruction was completely relieved, and normal breathing established.

Treatment and Prevention of Tuberculosis by Tuberculin Immunization.—Dr. William Litterer of Nashville stated that (1) experiments on animals demonstrated the possibility of creating immunity to tuberculosis by the use of the tuberculins. (2) The time was not far distant before individuals showing a tuberculous tendency would submit themselves to the repeated injections of some form of tuberculin as a means of prophylaxis against this disease. (3) The clinical method in the administration of tuberculin was far preferable to the one advocated by Wright, in which the estimation of the opsonic index was essential. (4) Tuberculin therapy was proving an essential aid in the treatment of tuberculosis, especially as an adjuvant to the hygienic, dietetic, and open-air treatment.

Dr. Louis Leroy thought some members of the profession had gone opsonin mad, and had followed opsonic work further than they had been justified in doing. The opsonic portion was simply an attachment to the value obtained from vaccine therapy. The advantage to be obtained from the injection of bacterial products had been known for many, many years, and it was only in casting about for a method to control this that the work of Wright was developed.

Tuberculosis.—The membership of the Tennessee State Committee of the International Congress on Tuberculosis presented a symposium on tuberculosis. Papers were read as follows: "Prophylaxis in Tuberculosis," by Dr. Y. L. Abernathy of Hill City; "Experimental Tuberculous Peritonitis," by Dr. William Litterer of Nashville; "Tuberculosis of the Cervical Lymphatic Nodes," by Dr. W. A. Bryan of Nashville; "How Best to Utilize Our Knowledge of the Communicability of Tuberculosis," by Dr. H. P. Coile of Knoxville; "The Marriage and Intermarriage of Tuberculous Subjects," by Dr. I. A. McSwain of Paris; "Bovine Tuberculosis," by Dr. M. Jacob of Knoxville.

Significance of Uterine Hemorrhage.—Dr. L. E. Burch of Nashville said that every case of uterine hemorrhage should be subjected to an immediate vaginal examination; that in the vast majority of cases this symptom was due to pelvic pathology, and that by carefully considering cancer, extrauterine pregnancy, abortion, endometritis, and fibroid tumors, and then by a process of exclusion, a correct diagnosis could usually be made. When pelvic pathology was discovered, it was generally necessary to resort to surgery to effect a cure.

Movable Kidney.—Dr. William D. Sumpter of Nashville said that the frequency of movable kidney demanded careful examination of position of the kidneys in vague abdominal pain. He spoke of the relation of movable kidney as a causative factor in appendicitis, diseases of the biliary passages, disturbances of the gastrointestinal tract, etc. He discussed the diagnostic methods of examination and the importance of differential diagnosis; palliative treatment, with its results; the indications for operative

treatment; choice of incision; method of fixation of the kidney, and the anatomical and therapeutical results of operation.

Papers were also read as follows: "Retention of Urine in a Female Infant Nine Weeks Old," by Dr. T. J. Happel of Trenton; "Some Symptoms produced by Appendicitis," by Dr. W. A. Bryan of Nashville; "Herniotomy," by Dr. George R. West of Chattanooga; "Conservative Surgery in Crushing Injuries," by Dr. Jere L. Crook of Jackson; "Diseases of the Frontal Sinus and Their Surgical Treatment," by Dr. C. M. Capps of Knoxville; "Ethics," by Dr. J. M. Kennedy of Knoxville; "Purulent Ophthalmia," by Dr. M. M. Cullom of Nashville; "The Treatment of Detachment of the Retina, with Reports of Cases," by Dr. L. B. Graddy of Nashville, and "Adenoids," by Dr. C. H. Davis of Knoxville.

Officers Elected.—The following officers were elected: *President,* Dr. B. D. Bosworth of Knoxville; *Vice-President for East Tennessee,* Dr. C. T. Carroll of Cleveland; *Vice-President for Middle Tennessee,* Dr. J. W. Brandau of Clarksville: *Vice-President for West Tennessee,* Dr. W. T. Blanton of Union City; *Secretary,* Dr. George H. Price of Nashville, reelected; *Treasurer,* Dr. W. C. Bilbro of Murfreesboro, reelected.

Nashville was selected as the next place for holding the annual meeting; time, second Tuesday in April, 1909.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 2, 1908.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Laryngology and Rhinology.

The Late Dr. D. B. St. John Roosa.—Dr. Charles L. Dana delivered a memorial address on the late Dr. Roosa.

The Diagnostic Value of Symptoms of the Larynx, Pharynx, and Nose in Nervous Diseases.—Dr. Thomas J. Harris read this paper. Affections of the nervous system presented symptoms of value and importance from a diagnostic standpoint in the throat and nose, whether they were true organic affections or only functional disorders such as the so-called neuroses. Of the two, the organic affections were the more important, and showed themselves chiefly in the larynx and were in the form of either sensory or motor disturbances. The motor manifestations represented either an excess or diminution of action. Excess of action was seen in spasms which might be tonic or clonic. Tonic spasms might take the form of spasms of the larynx, laryngeal crises, or ictus laryngus; clonic spasms might take the form of spasms, as rhythmic twitchings, or tremors. When an organic nerve lesion was present, it was most frequently one of diminished action or paralysis. These paralyses might involve the superior or inferior laryngeal nerve. A paralysis of the former was rare, while a paralysis of the inferior laryngeal nerve, almost without exception, involved the cricoarytenoideus posticus at the onset, and only at a late stage, if ever, attacked the adductors. This was a striking fact and its clinical significance was at once apparent. A posticus paralysis had to do with respiration. After a hasty review of the present day views on the innervation of the larynx, he considered how they might make use of them in a practical manner in diagnosis. This applied chiefly to affections of the medulla and below, although it was true that cerebral hemorrhage, tumors, abscess, gummata, and pseudobulbar palsy might produce motor changes in the larynx when extensive enough or properly situated. (1) Tabes dorsalis at times showed symptoms in the nose such as disturbances of the olfactory nerve resulting in anosmia or parosmia, but usually they were limited to the larynx in some form of paralysis. Unilateral or bilateral posticus paralysis might be regarded as characteristic of tabes. In the bilateral form the one symptom was gradually increasing inspiratory dyspnea, with expiration unaffected. Even more interesting were the various forms of laryngeal motor irritations in tabes. These included ataxia of the cords, giving rise to the characteristic scanning speech. (2) Laryngeal crises might occur early in the disease like the palsies, and might even precede the ocular manifestations. The laryngeal crisis was characterized by the simultaneous involvement of all the respiratory muscles, and so differed from an ordinary spasm of the larynx, with the cords immobile in the median line and their free borders taut; this would mean, in all probability, a central nerve lesion. If the picture should change in time to one showing the cords in the so-called cadaver position, *i.e.* midway between inspiration and expiration, with concave borders, they would know that the entire recurrent nerve had been involved, pointing to the progressive character of the lesion in the bulb. Sensory disturbances in connection with tabes were rare. (3) Multiple sclerosis of the brain and spinal cord would produce symptoms in the larynx almost if not quite as frequently as tabes. The common symptom present was a delay in the muscular action. This might take the form of tremor in phonation and an abnormal tendency to voice fatigue. There would be noted also the scanning speech with frequent interruptions by high-pitched explosive sounds. The voice was often raspy or hoarse. Occasionally they met with true paralysis, usually of the adductors. (4) Syringomyelia presented laryngeal symptoms, also motor in nature, and reduced reflex irritability of the posterior pharyngeal wall. (5) Progressive bulbar paralysis was especially characterized by symptoms referable to the tongue, lips, and larynx. The laryngeal symptoms did not appear with any such constancy as did the symptoms referable to the tongue. (6) Progressive muscular atrophy very commonly showed symptoms in the larynyx or pharynx, and these were usually of the nature of a paralysis, either of the entire throat and larynx, or more often of the larynx. (7) Neuroses, the functional nervous affections, often showed themselves in the upper air passages, and the two most commonly met with were paralysis agitans and hysteria. Paralysis agitans in a considerable number of cases gave rise to laryngeal symptoms, and usually of a motor character. In hysteria, nose and throat symptoms were frequently met with, and these might be either sensory or motor. Sensation was often affected. (8) Anesthesia of the mucous membrane of the nose and pharynx was frequent. The septum was wont to escape as well as the larynx. (9) Hyperesthesia and analgesia of the pharynx was quite frequent and took the form of a choking sensation, tickling, feeling of a foreign body, and the familiar globus hystericus. (10) Disturbances of coordination during phonation were common. Dysphonia spastica was the term used to describe the spastic form here. After considering a few other conditions which gave symptoms in the upper air passages, Dr. Harris concluded that two things had been shown, viz., (1) that pharyngolaryngeal symptoms in nervous diseases were deserving of more attention on the part of the neurologist than they had received up to the present time; (2) that no field offered greater opportunity to the laryngologist for original sudy and research than that which embraced the innervation of the larynx.

The Diagnostic Value of Symptoms of the Upper Respiratory Tract in Syphilis and Tuberculosis.—Dr Francke H. Bosworth read this paper. Tuberculosis of the nose was a clinical and pathological curiosity: many such cases had been reported in which the local disease in the nasal passages seemed to have connection with some serious lesion in the parts below. Tuberculosis in the lower pharynx, larynx, and buccal cavity was mainly of interest in the fact that it gave a certain clinical insight into the virulence of the disease. Clinically, it was observed that, as a rule, the nearer the tuberculous process involving the upper air tract approached the external world

the more virulent and hopeless the disease seemed to be. Thus, the fatality of laryngeal, pharyngeal, and lingual tuberculosis seemed to show an increasing ration of gravity in the order given. When, however, the manifestations of syphilis were considered, there was an entirely different story, and one in which the diagnosis was based upon ocular inspection. Syphilis was one of the most curious diseases with which they had to deal. The germ made its way into the system in such a way as not to leave a trace of the portal of entry. It lurked in the blood for months, oftentimes for years, giving no evidence of its existence, without causing any impairment of health, gaining strength year by year, and finally manifesting itself by some grave lesion which was commensurate in the large majority of instances with the length of time which had elapsed since the invasion. Its manifestations were often obscure and misleading, rendering a definite diagnosis impossible in many cases. This was undoubtedly true of other regions of the body, but when it invaded the mucous membrane of the upper air tract, it pursued, in the majority of the cases, a regular and orthodox course. This consisted merely in the invasion of the tissues by inflammatory corpuscles. The mucous patch was the result of the deposit of these inflammatory corpuscles in the epithelial layer of the mucous membrane, and occurred five or six weeks after the primary sore, or even longer. Later occurred the superficial ulcer; this resulted from a coagulation necrosis and involved the epithelium and the mucosa, and appeared as the shallow, ovoid ulcer, with necrotic tissue and purulent secretion. In gumma the deposit was not only in the epithelium and mucosa but in the submucous tissues beneath. These manifestations of syphilis in the nose, fauces, and larynx ran a somewhat different course. A primary sore occurring in the nose was a curiosity. The nasal cavity was the home of the gumma, but it was rarely observed owing to the fact that the necrosis and deep ulcers followed so rapidly that the gumma did not come under observation. Necrosis of the nasal bones was almost pathognomonic of syphilis and he said he could recall but one case of necrosis of the vomer which was not due to this disease. It was a view entertained by many that syphilis was a progressive disease, but Dr. Bosworth considered it an explosive one. The poison lurked in the system for months, gathering strength, virulence and activity, without manifesting itself in any form until finally it suddenly invaded one of the tissues of the body depositing these inflammatory corpuscles. Then it became for the time being a local disease; the gumma in the nose broke down into deep ulcers involving the whole mucous membrane as well as the periosteum. The sequestrum became wedged in, held firmly in the nasal cavity, and became a source of irritation, crust formation, fetid discharge, malodor, etc. The larynx was a favorable seat for the study of syphilis; the diagnosis was oftentimes very difficult. In the majority of the cases they had to do in the larynx with what he called "laryngitis deformans," an irregular thickening of the mucous membrane, with cicatricial sequelæ which seriously impaired the function of the larynx, and which presented appearances which were often puzzling. The manifestations of syphilis in the lower pharynx, faucial pillars, tonsils, palate, and uvula ran a regular course, and presented no eccentricities, and developed, as a rule, no deceptive appearances. Here appeared the "Dutch garden aspect." From a clinical point of view, it was a rather curious feature of syphilis that it manifested no marked tendency to transcend anatomical boundaries. Syphilis of the nose very rarely extended to the skin in front or into the pharynx behind. Syphilis of the lower pharynx very rarely extended above the border of the soft palate or the larynx below, while syphilis of the larynx, even more than cancer, showed a disposition to remain a laryngeal outbreak. In conclusion, he said he wished to emphasize the following: (1) The pharynx, beyond all other regions of the body, was a favorable site for the study of syphilitic outbreaks, and the one which, less than other regions, the disease was less liable to be mistaken. (2) The hesitancy of syphilitic outbreaks to transcend anatomical boundaries. (3) The fact that an outbreak of syphilis was self-limited, and showed no tendency to extend. The explosive theory of syphilis was one he believed to be worthy of consideration.

The Diagnostic Value of Symptoms of the Upper Air Tract in Rheumatism, Gout, and Diabetes.—Dr. Emil Mayer read this paper. He said that the first and most important relation of the upper air tract in rheumatism was the etiological factor. It was now generally accepted that rheumatism was a disease of the infectious type, and that some form of streptococcus was responsible, and there was a practical unanimity of opinion that the entrance into the system was obtained by way of the mouth through some part of the Waldeyer ring. The manner of entry was described. The various disease germs that found lodgment in the mouth found a general resistance to their attack by the bacteria of health. Reinforcements arriving to the attacking party, or a break in the epithelium, caused a portal of entry, and the lymph spaces were entered, then the glands, and infection ensued. There was a difference of opinion as to the entry of disease through any part of the mouth; also, as to whether the main point of entrance was the pharyngeal tonsil. Dr. Mayer quoted authorities to show that infection did arise by way of the faucial, pharyngeal, and lingual tonsils; in the majority of instances it originated in the pharyngeal tonsil. He also presented the negative side. He called attention to the fact that rheumatism, once established, might present itself as such in the pharynx and larynx, and that distinct rheumatic affections of the cricoarytenoid articulation had been shown to exist. Laryngologists had frequently made a diagnosis of a rheumatic affection of the upper air tract, subsequently eliciting a history of rheumatism. He called attention to the possibilities of symptoms of acute rheumatism caused by the presence of an abscess of the antrum of Highmore. Practically all that had been said of rheumatism applied to gout, except that in the latter there was a concurrent condition in the nose of a vasomotor type. These had been variously labelled as due to a lithemic or gouty diathesis. In regard to diabetes, there was an interesting chapter in the record of a few cases in which the sole complaints were a dryness in the throat and early fatigue in the use of the voice. There was no excessive thirst and no emaciation, and yet sugar was found in fairly large quantities. With a restricted diet, the throat symptoms promptly subsided. Dr. Mayer also called attention to furunculosis and perichondritis of the larynx, and finally to diabetic ulcerations of the throat. He concluded that infection in rheumatism and gout entered the system by way of the mouth, and that the chief point of entry seemed to be the pharyngeal tonsil. Rheumatism might affect as such the nose, pharynx and larynx; gout affected the larynx, but more frequently the nasal mucosa. Diabetes might be discovered very early by painstaking examination in certain laryngeal cases, a late symptom being furunculosis of the larynx, and, possibly, perichondritis. Fatal ulceration of the throat occasionally manifested itself in diabetes.

Dr. Alexander Lambert said that a more unsatisfactory condition in medical diagnosis did not exist than the efforts to distinguish gout from rheumatism. There was no pain in the muscles, joints, or other situations in the body, whatever was the cause, but what was called rheumatism. There were many mistakes made in what symptoms belonged to the disease. Gout and rheumatism were two widly different things, yet both were claimed to show equal manifestations in the tonsils and upper air passages. He believed the reason why most of the cases of rheumatism manifested themselves in the air passages was because most of them were cases of irregular gout. Gout was an autointoxication from whatever cause. It was to him very

remarkable to hear discussed and insisted upon the tonsillar entrance of rheumatism in the body. For ten years he had been seeking at Bellevue Hospital to learn how many cases of true rheumatism, polyarticular and in the large joints, showed a tonsillar infection, or even a history that the patient had ever had any infection of the tonsils. In those cases of polyarticular rheumatic infection, with involvement of the large joints, it was a very rare thing to find a history of tonsillar involvement in an adult's throat. Cases were occasionally met with pain in the tonsils lasting a few days, later with cardiac involvement, and then a joint infection. But in cases of gout it was rather rare not to find some manifestations in the throat. The cases quoted by Dr. Mayer were those in which the giving of aspirin cured the rheumatic infection, and this to him was of interest because, in Dr. Lambert's experience, aspirin in true rheumatism failed to give relief; whereas, in gout relief followed its administration. Aspirin would clear up a mild attack of gout, and, in severe cases, it would control the pain. In children he believed there were more cases than in adults in which a bilateral tonsillar infection proceeded the other manifestations. This might be due to the fact that the lymphatic tissues in children were better filters and held the infection better than the adult lymphatics did. Since Dr. Mayer had asked him to take part in the discussion, he had taken more than usual care in a large number of rheumatic patients, to see if their throats hurt them, or if there were other physical throat manifestations before the true rheumatism came on, and only such cases with involvement of large joints were taken into consideration. In not a single case this winter, during the past three months, was he able to obtain a confession that the throat hurt, or the tonsils were inflamed, before the invasion of the rheumatic infection.

Dr. William M. Leszynsky said that the larynx received its innervation from the vagus and accessorius nuclei, particularly through the pneumogastric nerve and its branches, any pathological process in the region of the nucleus ambiguus or in the course of this nerve would occasion tremor, spasm, or paralysis of laryngeal muscles. This was known to occur in various affections of the pons and medulla, in tabes, syringomyelia, disseminated sclerosis, progressive spinal muscular atrophy, etc. Moreover, such laryngeal symptoms also arose in the course of paralysis agitans, convulsive tic, asthenic bulbar palsy, and hysteria. In the so-called polioencephalitis inferior, or bulbar paralysis, in which the symptoms were characteristic and essential, the larynx was never affected alone without involvement of the lips, tongue, palate, or pharynx. It would thus be seen that all degenerative or inflammatory diseases of the cerebrospinal system were more or less frequently accompanied or complicated by implication of the bulbar nuclei. The diagnosis of diseases of the nervous system could not be made from the presence of an isolated laryngeal or pharyngeal paralysis. While the latter condition might be highly suggestive, in no sense could it be considered pathognomonic. When laryngeal tremor, spasm, or paralysis was the result of such general disease, other indications would invariably be found. As tabes was the commonest type of organic nervous disorder, his further remarks were limited to this affection. A person might suffer for several years from tabetic laryngeal crises without any of the obtrusive symptoms of tabes, such as incoordination, pains, etc., yet upon examination one might find unmistakable signs of the disease. Such a patient was now under his care. While it was an interesting fact that quite a large number of cases of chronic tabetics had disturbance of the innervation of the laryngeal muscles, in the majority of instances this was of minor importance as compared with other pronounced manifestations. Exceptionally, a laryngeal crisis had been known to terminate fatally. Transitory laryngeal paralysis was rare, in contrast with paralysis of the ocular muscles. In the cervical type of tabes, in which the arms were first affected, laryngeal crises and posticus paralysis with bulbar symptoms were more likely to arise, the lower extremities becoming involved later in the course of the disease. He suggested that loss of knee jerks with preserved muscular power in the lower extremities, and loss of the pupillary light reflex with preserved vision, when found combined, might be interpreted as presumptive evidence of tabes or cerebrospinal syphilis. It should also be borne in mind that in many early cases of tabes there was no ataxia whatever. Finally, the diagnostic value of symptoms of the upper respiratory tract in the various diseases of the nervous system depended entirely upon the correlation and association with other symptoms.

Dr. L. Duncan Bulkley said that he had seen a great many cases in which the lesions in the mouth were supposed to have been syphilitic, and yet were not; there were at least half a dozen conditions met with in the mouth that made the diagnosis from syphilis somewhat difficult. For instance, eczematous lesions about the lips often suggested a syphilitic affair, and so did lupus erythematosus. Leucoplakia in the mouth was often thought to be syphilitic, although this occurred almost invariably in smokers. Again, the later lesions of syphilis, supposedly gummatous in character, were often mistaken for epithelioma. With regard to the tonsils being the site of invasion, syphilis of the tonsil, or the primary chancre of the tonsil, was more common than generally believed, and Dr. Bulkley had reported fifteen undoubted cases some years ago, and since then he had seen other cases. Chancre occurring about the mouth was very common; whereas chancre in the nostril was not so common.

Dr. William K. Simpson said he did not believe that the time had come when one should depend entirely upon the laboratory findings; those who worked in the laboratories were just as much dependent upon the clinician as the clinician was upon them. He had not seen any great relation between rheumatism and tonsillitis, and he had made investigations clinically, as Dr. Lambert had, to learn if patients with marked attacks of tonsillitis had ever given signs of rheumatism; and, *vice versa*, whether any patients with acute polyarticular rheumatism had ever had signs of a tonsillitis. He had not met with such instances. Dr. Simpson believed that often general diseases might be diagnosed by conditions occurring in the upper air tract. For instance, a unilateral paralysis of the vocal cords might be one of the earliest signs of an aneurysm. He drew attention to the importance of examining the throat in latent cases of syphilis, in the various neuralgias of the face, and in sinus disease. In cases of supraorbital neuralgia, without any history of a purulent discharge at all, the *x*-ray might show frontal sinus involvement, and operation would enable one to remove a large quantity of pus and clear up the condition. He said it was often a difficult matter to make a clinical differentiation between the various ulcerative lesions found in the throat.

Dr. Thomas J. Harris, speaking in reference to syphilis of the nose, said that he had seen at least three or more cases in which the patients complained only of symptoms usually associated with asthma, such as sneezing, nasal obstruction, and watery discharge. The patients gave no history of syphilis, and were very misleading. In each of these cases the condition was cured by the administration of the antisyphilitic treatment.

Dr. Emil Mayer asked what was rheumatism, and what was gout, and said that, in his paper, he had quoted some of the best writers in the world. Was the invasion by way of the tonsils or the tonsillar ring, or was it not? There was hardly a practitioner he had met that had not, at some time or other, been surprised because his patient had an attack of endocarditis. He recalled the case of a boy whom he had known from birth, and had examined from time to time. To his great surprise, after a fainting attack, he was found to be a victim of endocarditis, and he learned that four or five weeks previously the boy had had an attack of follicular tonsillitis.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 23, 1908.

First Vice-President Dr. H. Seymour Houghton in the Chair.

The Correlation of Clinician, Pathologist, and Laity.—Dr. Bond Stow read this paper. He showed in detail the extent to which the clinician was dependent upon the pathologist, and urged upon the physician that it was his duty to avail himself of all the aid that the laboratory could give. It was difficult to understand how physicians had formerly practised medicine without this assistance. The practice of medicine was based upon the fundamental principle of cause and effect. The physician must be skilled in inductive reasoning; he must marshal his facts and reason out his case much as the lawyer did. He held up the ideal of raising the practice of medicine to a science; it was now too empirical. He urged very strongly that the physician should obtain an autopsy whenever possible, especially if there was any doubt as to the cause of death. He showed that in many instances, especially in certain classes of diseases, it was utterly impossible, in the present state of our knowledge, for the physician to state the exact cause of death, and cited the instance of a prominent European clinician, who acknowledged that he had made a correct diagnosis in only 60 per cent. of the cases upon which autopsies had been performed; of course, this was in a selected and obscure class of cases, such as abscess of the liver, miliary tuberculosis, etc. The laity should be educated to understand the value of autopsy work as an aid to the physician in diagnosis. With the symptoms observed at the bedside, the revelations revealed in the laboratory and the post-mortem table, there was a wide field from which to gain facts that would enable the practitioner to avoid repeating his mistakes. The importance of the post-mortem finding should be so impressed upon the laity that, if the physician did not ask for an autopsy, they should demand it.

Dr. Beverly Robinson said that, while he agreed with Dr. Bond Stow as to the importance of pathological findings to the laity as a means of correcting imperfect knowledge and of preventing future mistakes, he thought that at times one must pay attention to the relief of symptoms so long as the knowledge of patnological changes was as uncertain and as unsatisfactory as at present. He had sometimes found in the post-mortem room, despite all available knowledge, literally nothing to account for pain, suffering, and death; again he had seen pathological lesions, multiple and profound, and the patient had lived long years with scarcely a pain or an ache. Again lesions might be present, and yet one could not be sure that they had caused the pain of which the patient complained. In how many cases investigated in the post-mortem room were the lesions discovered to be the cause, immediately or approximately, of the death which has occurred? The limitations of human vision to mere structural defects of pathological origin, as a cause of disease, were misleading. There were instances where, supposedly by reason of what had been found in other advanced cases, certain pathological changes had existed at a certain period during life. Could one prove their existence absolutely? Fortunately for many of the human kind, medicine must always remain a kindly and sympathetic art, and not a science. He had frequented the hospital ward and the post-mortem room for many years, and still affirmed that much could be learned in private practice from patients who did not die and for whom pathological and bacteriological research could avail but little in ameliorating their lot or promoting cure. He was not aware, save in a very few acute diseases that, despite the march of science, we had shortened the duration of diseases by a day's length, nor was he aware of any chronic disease that was really cured by medicine of any kind *solely*. Surgery had done marvelous things in a few cases, but often she interfered at the cost later of ultimate good to the patient. Nature and nature's laws were hard to know, and we were compelled to fall back upon the wisdom that had stood the test of time. One great difficulty in the way of pure science ever getting the best that could be had in therapeutic results was the necessary ignorance of the personal factor in disease. This was all-important in achieving success. He urged the crying need of the aspiring, ambitious men of to-day not to ignore or forget the men of like fiber who had gone before. The old physicians had been "good and true men" and had accomplished not a little. Pathology and the dead house, morbid anatomy and gross pathology, and even microscopical researches were not all new. They had followed others, and others would follow them with still newer processes and newer findings, but much that was old would remain true for many a year, if, indeed, it ever died. He said this was a plea for the honest, observing physicians, who wanted some man to hold up their end a little, and not leave them feeling that unless they lived in the laboratory and dead room there was no truth and usefulness available even to the most painstaking and loyal servant of our great guild.

The Public Hospital System of New York City.—Hon. R. W. Hebberd, Commissioner of Public Charities, spoke on this subject (by invitation). He prefaced his remarks by stating that those present no doubt knew more about the hospital system in New York City than he, and indeed it was a question whether there was a hospital system. He knew of no city under whose government three departments tried to manage the hospitals. The Department of Public Charities, Bellevue and the Allied Hospitals, and the hospitals under the control of the Department of Health all took very much the same class of patients, but as there was no head for the hospital department and no system, the hospitals grew up in spots, leaving certain localities entirely without needed hospitals. Nearly twelve million dollars had been planned to be spent in the Borough of Manhattan. Now Manhattan was not growing as rapidly as the other boroughs, and there were parts of Brooklyn and the other boroughs very much in need of hospitals; consequently there was no logical equity in this way of spending money. The City of London had 20,000 free beds in public hospitals, while New York, which was nearly as large, had less than 5,000. No one knew where the function of one of the departments ended and another began. The Department of Public Charities had been trying to get a hospital for tuberculosis on Staten Island, but the court held that only the Department of Health had the right to look after consumptives; consequently the work was held up. The Mayor two years ago appointed a committee to investigate hospital administration; this committee was now about ready to render its report. As a member of the committee it seemed to him the city should have a hospital department under a single commissioner. This commissioner should be a physician trained in business matters. When physicians had been placed at the heads of departments they had done so remarkably well that it could no longer be said they lacked practical business ability. He said there was no reason why the Board of Health should conduct hospitals any more than that the Police Department should conduct penitentiaries. If there was only one commissioner there would be no friction; he could locate hospitals where they were needed, putting the larger institutions near educational centers, and smaller ones where they were the most needed. They had on Blackwell's Island an opportunity for a great hospital park; this had been neglected. Randall's Island could be made one of the finest properties in

the city for children, when the State took the feeble-minded and dependent children, as it would soon do. He hoped the medical profession and their societies would cooperate in bringing about these reforms.

The Ambulance System of Public and Private Hospitals.—Nathan Bijur, Esq., compared the working of the Fire Department with that of the ambulance system. He related the story of the Irishman who said he preferred to be in a railroad accident to being in a steamboat accident, because, when you were in a railroad accident there you were; but when you were in a steamboat accident, where were you? When you sent in a fire alarm, there you were; but when you sent in an ambulance call, where were you? The fire alarm system was perfect. All alarms went to headquarters, and so minutely was the system worked out, that if a fire was only twenty yards further from one fire house than from another; the nearer one responded. At headquarters they always knew just when the apparatus went out, when it returned, and when it was ready to go again. It was fair to acknowledge that the lack of system in regard to the ambulances was not due to private hospitals. Many people did not know whether to send to a hospital for an ambulance, or where. It should be generally known that ambulance calls should be sent to police headquarters, as this department has several telephone operators, whose special work was to attend to the ambulance calls. The difficulty was that the Police Department never knew whether an ambulance was in or out; whether it had responded to a call, or when it returned. There was also an absence of system in stationing ambulances. There was no ambulance on the entire west side, from Hudson Street Hospital up to Roosevelt, and then none until the Hood Wright Hospital. On the lower east side there were three very near together. No one seemed to be responsible if an ambulance did not respond to a call. If a hospital did not do its duty the ambulance service was taken from it. The fireman always had about the same duties to perform, whereas the ambulance surgeon never knew what awaited him. He had endeavored to draw up a plan for an ambulance service and proposed that there be one head, and that a bureau be established and that the city be adequately districted in accord with the population. The call should come to a central bureau. All apparatus should belong to the city, and all officials be employees of the city. There should be some emergency ambulances and some transfer ambulances for use when there was no great hurry. It was a question whether public authority be vested with this power, but it seemed to him that there was no opportunity for favoritism in this system.

Dr. Theodore C. Janeway said that those in contact with Mr. Hebberd would approve of his plan if Mr. Hebberd would be the Commissioner. He had shown an unusual ability in grasping the features of hospital administration, especially in reference to the educational factor. The only way to secure the best care in hospitals was to locate them in the vicinity of medical colleges. The fact that this subject had been discussed was an omen of what was to come. The profession had a fear of change lest it might affect the interests of the physician. He did not think that the Borough of Manhattan should develop her own hospitals at the expense of the needs of other boroughs. He thought the hospitals in connection with educational centers should receive special attention. If our hospital system was to develop like that of European hospitals, it would be by attracting the best teachers and investigators of the day. He thought that if hospitals were split up into smaller institutions with different heads, they would have poor records. Many medical students were now attracted to Philadelphia because the opportunity for hospital practice was better there than here; there the colleges controlled the hospitals. The profession need not fear a change because more men would be needed than at present; they would be graded and each would have an opportunity to rise to the head; but now no one had such a chance. Medical sentiment should first be educated.

Mr. Ludlum, Superintendent of New York Hospital, continued the discussion (by invitation). He said that the subject had been thoroughly covered and he could only endorse what had already been said. It was a matter of hearty congratulation that this subject had at last been taken up and put in shape so that it could be presented to the Mayor, and it would be a great disappointment if the citizens did not create a public sentiment that would lead to a consummation of the proposed project. The duplication of effort, the numerous managing boards, and the extravagant expenditure indicated that all hospitals should be under one board of management. The Commissioner should be longer lived than one political term. Ten years should be the shortest time that he would hold office. The scope of the commission that was appointed had been widened. The building of a new Bellevue could not be a mistake. Those who recollected the Bellevue Hospital of twenty-five years ago could not believe it possible that the institution was as it was to-day. The public did not appreciate the work of that board. What was needed was centralization. When all hospitals were under one management, or one man, they could have a satisfactory system. What was true of the hospitals was also true of the ambulance service. The city had never had an ambulance service. As many ambulances were maintained by private hospitals they were located arbitrarily. There was no necessary connection between an ambulance service and the hospital. The ambulance service belonged to the city, and not to the hospital. He thought something should be said in favor of the ambulance surgeon, who received nothing but abuse continually. He was a hard worked individual, his work was well done, and deserved the praise of the community. If a private institution wished to maintain an ambulance service, he thought it should be permitted to do so; but it should come into the city system. He hoped that public opinion would carry to a successful issue any recommendations that the commission might make.

Hon. R. W. Hebberd closed the discussion by hoping that the report of the commission could be put into practical operation.

Plea for a Needed Custodial Asylum.—Dr. E. Eliot Harris, Chairman of the Committee on Legislation, read the Armstrong Bill, and asked that the Society use its influence in securing the passage of this measure. The Armstrong Bill provided for the appropriation of $486,000 for a custodial asylum, to be located near Haverstraw. New York City paid 75 per cent. of the State tax for the support of four existing western, inadequate, and not easily accessible asylums. It supported in its own institution 1,100 of the feeble minded, and 1,800 indigent epileptics. The need of this proposed Eastern Custodial Asylum was very pressing; the site selected could be purchased cheaply at present, but would soon be dear, and its accessibility to New York City made it highly desirable. For these reasons a set of resolutions was drawn and sent to each member of the society, asking that he should use his personal influence in securing this much-needed legislation.

Endowed Beds for Physicians.— The announcement was made that Maria L. Campbell had given St. Luke's Hospital $20,000, to be used as an endowment fund for the support of beds for the use of physicians. The use of these beds could be secured by application to the superintendent of the hospital.

Kissing Games Forbidden.—The London County Council has issued an ordinance forbidding children attending County Council schools to play games in which kissing forms a part. The head teachers are instructed to see that such games are discontinued. The reason for the prohibition is contained in a sentence of the ordinance reading: "On medical grounds the practice is considered undesirable."

State Medical Licensing Boards.

STATE EXAMINATION QUESTIONS.

Virginia State Medical Examining Board.

Staunton, December 10, 1907.

ANATOMY.

1. Describe the upper extremity of the ulna.
2. Describe the ligaments of the hip joint.
3. Describe the pectoralis major muscle, giving origin, insertion, actions, and shape.
4. Give the relations of the cervical portion of the left common carotid artery.
5. Describe the phrenic nerve, giving origin, course and distribution.
6. Describe the receptaculum chyli and thoracic duct.
7. Give the structure of the testis, and name its investing tunics.
8. Describe the inguinal canal.

PHYSIOLOGY.

1. What changes does the blood in the pulmonary artery undergo in its passage through the lungs?
2. Describe the pancreatic juice, naming its ferments and describing the part each plays in digestion.
3. In what manner is heat given off from the body and from what sources does the greatest loss occur?
4. What circumstances influence secretion in a gland?
5. Describe vomiting and its mechanism.

CHEMISTRY.

1. What is meant by the terms synthetic chemistry, analytical chemistry, physiological chemistry, quantitative and qualitative analysis?
2. What is meant by the boiling and the melting of a substance? By sublimation? By distillation?
3. What is the chemical difference between ferrous and ferric salts? Give formulæ showing the difference.
4. How does sodium occur in nature? Give formulæ of three sodium salts. Give process for manufacturing sodium carbonate on large scale.
5. What are carbohydrates? How do they differ from hydrocarbons?
6. Explain the composition and manufacture of soap, and state the difference between hard and soft soaps.

MATERIA MEDICA.

1. Name the official preparations of opium and belladonna. Give dose of each.
2. State effect of sodium carbonate and bicarbonate on gastric digestion before and after meals.
3. Define an alkaloid; name six, with dose of each.
4. Give an example of the following, with dose: Antispasmodics, antipyretics, hypnotics, narcotics, emetics, expectorants, diuretics, anthelmintics.
5. Write fifteen lines on the physiological action of alcohol.
6. Symptoms of phosphorus poisoning.

THERAPEUTICS.

1. Mention the therapeutic uses of the syrup of hydriodic acid.
2. What are the therapeutic uses of salol? (b) What symptoms indicate the discontinuance of its use? (c) In what pathological conditions is it contraindicated?
3. Mention the therapeutic uses, external and internal, of nitrate of silver.
4. In what pathological conditions is uva ursi used?
5. Give the indications for the therapeutic uses of hyoscyamus.
6. Give the common name, the dose, and the therapeutic uses of potassium bitartrate.

TOXICOLOGY.

1. Give test for arsenic poisoning.
2. Give symptoms and treatment of carbolic acid poisoning.
3. Give diagnosis and treatment of cocaine poisoning.

MEDICAL JURISPRUDENCE.

1. Give signs of pregnancy at first, and third, and sixth months.
2. Give postmortem evidences of miscarriage.
3. What is the period of gestation in the human family? How is it estimated?

PRACTICE.

1. Distinguish between lithemia and uremia.
2. What functions are at fault in their causation, and to what end should remedial measures be directed?
3. Give cause and clinical symptoms of diphtheria.
4. How, where and in what quantities should antitoxin be administered?
5. What is infantile scurvy? How remedied?
6. Give treatment for delirium tremens.
7. State cause and give treatment for the most common form of malarial fever.
8. Outline prophylactic measures against malaria.
9. Give symptoms and treatment of lobar pneumonia.
10. Give symptoms, and outline management, of a case of paralysis agitans.
11. Give treatment of enuresis nocturna.
12. Give symptoms and treatment for arteriosclerosis.

SURGERY.

1. Describe the operation of excision of the elbow joint, and state when it is indicated.
2. What is lupus vulgaris? Give diagnosis and treatment.
3. Describe every detail in the operation for ligation of the external iliac artery.
4. Give diagnosis and treatment of fracture of the outer third of the clavicle.
5. What is a sprained joint? Give treatment and prognosis.
6. What is rickets? Give causes, symptoms, prognosis, and treatment.
7. There are three classes of knee-joint inflammation: Synovitis, capsular arthritis and osteoarthritis. Differentiate them.
8. You are called to see a patient who is totally unconscious and insensible to pain; there are no movements of any kind. The pulse is slow, the respiration slow and probably shallow, and the pupils either widely dilated or closely contracted, or one pupil contracted and the other dilated. On inquiry, you get the history of a fall or blow on the head, yet the visible evidence of such is slight. What would be your diagnosis and treatment?

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. Describe in detail the certain signs of pregnancy.
2. Give the symptoms and treatment of toxemia of pregnancy.
3. Management of the mother from the beginning to the third stage of labor, and to the fourth day of the puerperium.
4. Name the causes that may give rise to fever during the puerperium.
5. What are the most frequent infective agents, in the causation of pelvic abscesses, mentioning the usual sites of such abscesses?
6. What cogent reasons may be urged for the utmost conservatism in operations upon the tubes and ovaries?
7. Give the most efficient treatment for urethral caruncle.
8. Differentiate spasmodic from membranous croup; treatment of the latter.
9. What diseases are conveyed by cow's milk, and what prophylactic rules should be instituted in such cases?
10. Give the etiology, symptomatology, and differential diagnosis of infantile scurvy.

LARYNGOLOGY.

1. Give symptoms, etiology, prognosis and treatment of œdema of larynx.
2. Define laryngismus stridulus, its symptoms and treatment.
3. Name most common causes, symptoms and the precaution to be taken in opening retropharyngeal abscesses.

RHINOLOGY.

1. Excluding traumatic and local causes, what diseases affecting the composition and circulation of the blood frequently cause epistaxis?
2. Describe objective and subjective symptoms and treatment of postnasal adenoid hypertrophy.

OTOLOGY.

1. For relief of what condition should puncture of drum-membrane be performed by the surgeon?
2. What are the two most frequent causes of deafness? Give treatment of each class.

OPHTHALMOLOGY.

1. Name the respective diseased conditions under which occur, viz.: (*a*) Yellow sclerotic, (*b*) bluish-white or pearl sclerotic, (*c*) an inflamed or injected conjunctiva.
2. Name most common causes and varieties of iritis, with symptoms and treatment.
3. What symptom in eye disease would indicate glaucoma in its early state? Explain importance of its early recognition. What is best treatment, and, if successful, what benefit is to be anticipated?

NEUROLOGY.

1. Give the diagnosis and prognosis of epilepsy.
2. Give definition and commonest causes of multiple neuritis.
3. Give the treatment of migraine (sick-headache).

PATHOLOGY.

1. Explain the difference between degeneration and infiltration.
2. Name the varieties of chronic nephritis, and state how they differ pathologically.
3. What is ascites? State its causes.
4. Name the tumors which have epithelium as a physiological prototype, and state which are malignant and which benign.
5. Explain the difference between puerperal septicemia and sapremia (septic intoxication).
6. Give the nature and origin of pus cells, and the origin of the liquid of pus.

BACTERIOLOGY.

1. Describe the *Streptococcus pyogenes*, naming some of the most important pathological conditions caused by it.
2. Give the bacteriology of catarrhal pneumonia.
3. Give the bacteriology of dysentery.

HYGIENE.

1. In making a qualitative test of drinking water, what impurities should be sought for?
2. What is the duty of the State to persons imprisoned for crime.
3. Give periods of incubation of measles, smallpox, diphtheria, scarlet fever, whooping cough and typhoid fever.

HISTOLOGY.

1. Describe the malpighian body in the kidney.
2. What type of gland is the thyroid? Describe its structure.

EMBRYOLOGY.

1. Describe the fertilization of the ovum.
2. Describe the development of the primitive alimentary canal.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

VIRGINIA STATE MEDICAL EXAMINING BOARD.

Staunton, December 10, 1907.

PHYSIOLOGY.

1. In its passage through the lungs, the blood in the pulmonary artery: (1) becomes cooled; (2) becomes a brighter red color; (3) gains oxygen (about 10 or 12 volumes); (4) loses carbon dioxide (about 7 volumes).

2. The pancreatic juice is a clear, viscid, alkaline fluid, and contains about three per cent. solids.

It contains four ferments: (1) *Trypsin*, which changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; (2) *Amylopsin*, which converts starches into maltose; (3) *Steapsin*, which emulsifies and saponifies fats; and (4) a ferment which curdles the casein of milk.

3. Heat is given off from the body by conduction, convection, radiation, and evaporation of fluid from the surface of the body; also through the urine, feces, and expired air. The greatest loss occurs from the skin.

4. The circumstances which influence secretion in a gland, are: Variations in the quantity of blood supplied to the gland, variations in the nerve impulses conveyed to the gland, various mental conditions, and certain drugs.

5. *Vomiting* is generally preceded by nausea and an increased flow of saliva. Then follow a deep and prolonged inspiration, the closure of the glottis, and fixation of the diaphragm. The abdominal muscles then contract and press the stomach against the fixed diaphragm. The cardiac orifice of the stomach relaxes, the other muscular fibers of the stomach contract, and there is a reversed peristalsis in the esophagus. The *center* for vomiting is in the medulla.

CHEMISTRY.

1. *Synthetic chemistry* is that branch of chemistry which is concerned with the building up of more complex substances from simpler substances or elements.

Analytical chemistry is that branch of chemistry which is concerned with the resolving of more complex substances into simpler substances or elements.

Physiological chemistry is that branch of chemistry which is concerned with the composition and changes in composition of living things, both in normal and abnormal conditions.

Quantitative analysis is concerned with the determination of the quantities of the various components in a given substance.

Qualitative analysis is concerned with the determination of the nature of the components in a given substance.

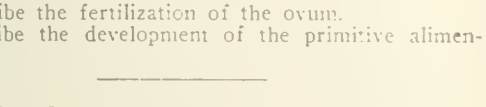
2. *Boiling* is the rapid conversion of a liquid into a gas, at a fixed temperature.

Melting is the passage of a solid body into the liquid state by the action of heat.

Sublimation is the conversion of a solid into a gas (without passing through the liquid state) and the reconversion of the gas into a solid. *Example*:—Sulphur can be sublimed by heating in a suitable apparatus.

Distillation is the conversion of a liquid into a gas, followed by the reconversion of the gas into a liquid. *Example*:—The distillation of water.

3. In *ferrous* salts, the atom of iron is bivalent. In *ferric* salts, the atom of iron is quadrivalent, and two such atoms are connected producing a double atom with a valence of six.



4. Sodium occurs in nature in combination, chiefly as the chloride; also, to a lesser extent, as the carbonate, nitrate, sulphate, etc. Formulæ of three sodium salts:—Sodium chloride, NaCl; Sodium nitrate, $NaNO_3$; Sodium sulphate, Na_2SO_4.

Sodium carbonate is manufactured on a large scale by the Leblanc process or by the Solvay process. In the latter process ammonium bicarbonate and sodium chloride react upon each other with the production of ammonium chloride and sodium bicarbonate:

$$NH_4HCO_3 + NaCl = NH_4Cl + NaHCO_3.$$

The sodium bicarbonate is then dried and heated, when it is decomposed into Na_2CO_3, H_2O, and CO_2.

5. *Carbohydrates* were formerly defined as substances of unknown constitution, composed of carbon, hydrogen, and oxygen; the last two being in the proportion to form water.

Hydrocarbons are compounds containing only carbon and hydrogen.

6. Soaps are the alkali salts of oleic, palmitic, and stearic acids.

They are obtained by boiling glyceryl oleate with sodium hydroxide or potassium hydroxide.

The hard soaps contain sodium; and the soft soaps potassium.

MATERIA MEDICA.

1. OPIUM. *Official preparations, and dose*:—Pulvis opii, gr. j; extractum opii, gr. ss; pulvis ipecacuanhæ et opii, gr. vij ss; acetum opii, ♏viij; tinctura opii, ♏viij; tinctura opii camphorata, ʒij; tinctura opii deodorata, ♏viij; tinctura ipecacuanhæ et opii, ♏viij; vinum opii, ♏viij.

BELLADONNA. *Official preparations, and dose*:—Extractum belladonnæ foliorum, gr. 1/5; tinctura belladonnæ foliorum, ♏viij; fluidextractum belladonnæ radicis, ♏j.

2. Given before meals, they increase the acid secretion of the stomach; given after meals, they tend to neutralize the acidity of the stomach contents.

3. An *alkaloid* is an organic, nitrogenized substance, alkaline in reaction, and capable of combining with acids to form salts in the same way that ammonia does.

Strychnine sulphate, gr. 1/64; morphine sulphate, gr. 1/4; atropine sulphate, gr. 1/150; aconitine, gr. 1/400; apomorphine hydrochloride, gr. 1/10 (as an emetic); quinine sulphate, gr. iv.

4.

Antispasmodic	Tincture of valerian, ʒj.
Antipyretic	Tincture of aconite, ♏x.
Hypnotic	Chloral hydrate, gr. xv-xx.
Narcotic	Morphine sulphate, gr. 1/4.
Emetic	Apomorphine hydrochloride, gr. 1/10.
Expectorant	Fluid extract of squill, ♏ij.
Diuretic	Potassium acetate, gr. xxx.
Anthelmintic	Pelletierine tannate, gr. iv.

5. Alcohol, *externally*, acts as a refrigerant, an astringent, a disinfectant, an anhidrotic; it also hardens the skin. *Internally*, it sharpens the appetite, is a digestant, a diuretic, a diaphoretic, is slightly antipyretic, it increases the force and rate of the heart beat and pulse, it is a vasodilator especially to the vessels of the skin, it causes an increase in the blood pressure, it is at first a slight nervous stimulant, but afterwards is a depressant; in large doses it is a narcotic, and then causes a reduction of body temperature.

6. *Symptoms of acute phosphorus poisoning*: "Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours, pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs, and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually, about the fourth day, the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies." —(Witthaus' *Essentials of Chemistry.*)

THERAPEUTICS.

2. *The therapeutic uses of salol* are: As a disinfectant, in inflammation of the mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera.

(*b*) *Symptoms indicating its discontinuance*, are: Smoky color of the urine like that of phenol poisoning.

(*c*) *It is contraindicated* in acute inflammations of the kidney.

3. NITRATE OF SILVER, is used *externally*, for: Conjunctivitis; granular lids; pruritus of genitals or anus; inflammations of the mouth, pharynx, fauces; orchitis and epididymitis; and to prevent the pitting of smallpox; it is also said to abort bedsores and boils.

Internally, it is used: In chronic gastric catarrh, gastritis, and gastric ulcer; intestinal ulceration, epilepsy, and chorea.

4. *Uva ursi* is used in: Pyelitis, cystitis, urethritis, chronic gonorrhea; and sometimes as a mild diuretic.

5. *Indications for the therapeutic uses of hyoscyamus*, are: Whooping cough, colic, nervous cough, asthma, hiccough, irritable bladder, as an antispasmodic, to diminish secretions, dysmenorrhea, neuralgia.

6. POTASSIUM BITARTRATE. *Common name*, Cream of tartar; dose, gr. XXX;

Therapeutic uses: As a diuretic, in chronic nephritis, to alkalinize the urine, to remove dropsy.

TOXICOLOGY.

1. *Test of arsenic poisoning*: Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

2. *Symptoms of carbolic acid poisoning*: Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

Treatment: Emetics, white of egg, stimulants. Alcohol is said to be antidotal.

3. In *cocaine poisoning* there will be found pain and fullness in the head, pulse first quick, later feeble and slow, extremities cold. The symptoms are not constant.

Treatment consists in the administration of ammonia or coffee; morphine, strychnine, chloroform, and ether have all been suggested. The safest plan is to treat whatever symptoms are present.

The *antidote* is said to be amyl nitrite.

SURGERY.

2. *Lupus vulgaris* is a tuberculous infection of the skin; it is generally found upon the face, particularly the nose and cheeks. It begins as a pinkish nodule which is painless, and spreads to other nodules and generally ends in ulceration with destruction of mucous membrane or cartilage. It is to be diagnosed: From (1) *Lupus erythematosus*, which is not supposed to be tuberculous, which is a symmetrical erythema with "butterfly wings," and which does not ulcerate. (2) From *Syphilitic ulceration*, in which the history of the case will help in the diagnosis, the ulcers are characteristic, and respond to syphilitic treatment. (3) From *Epithelioma*, which is more painful, occurs later in life, does not tend to heal, and the ulcer has everted edges.

Treatment. In the early stages the small nodule may be excised. If not seen till later, curettage with a sharp spoon, followed by cauterization with pure carbolic acid, has been recommended. This can be repeated at intervals of three or four weeks if necessary. Finsen light and tuberculin have also been used.

5. A *sprain* is a self-reduced dislocation; generally due to a twist, in which some fibers of the ligaments are stretched or torn, and the synovial membrane contused.

Treatment consists in at once applying cold cloths and compression; the limb should be raised and the joint fixed and firmly bandaged, and kept at rest till the swelling and pain have disappeared. Later on, after the swelling has subsided, hot fomentations and massage are indicated. Passive motion, and later on active motion should be enforced. Adhesive plaster strips placed so as to afford support and fixation without interfering with the circulation in the limb, are recommended.

Prognosis is good, unless complications are present; the chief danger is ankylosis.

7. In *synovitis*, the synovial membrane alone is inflamed; and the other structures of the joint are unaffected.

In *capsular arthritis*, all the structures of the joint (synovial membrane, cartilage, bones, ligaments) are inflamed.

In *osteoarthritis*, besides the involvement of the parts named in capsular arthritis, new masses of bone are formed.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. *The certain signs of pregnancy* are: (1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical souffle.

2. TOXEMIA OF PREGNANCY. The symptoms are:— "Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions." (King's *Manual of Obstetrics.*)

The line of *treatment* as laid down by Edgar is as follows: For *preventive treatment*: (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

The *curative treatment* includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

4. The causes that may give rise to fever during the puerperium, are pathogenic bacteria (the chief of which are: *Streptococcus pyogenes, Staphylococcus pyogenes aureus, Staphylococcus pyogenes citreus, Staphylococcus pyogenes albus, Bacterium coli commune, Bacillus pyocyaneus*) introduced into the genital canal of the patient. The most common means of such infection are the hands of the physician, nurse, midwife, or of the patient herself; unclean instruments and catheters; coitus during the time immediately preceding labor; contact with secretions from wounds of any kind, no matter where situated; general unhygienic surroundings, and contact with a patient suffering from scarlet fever or erysipelas on the part of any one attending on the woman.

7. The most efficient treatment for urethral caruncle, is complete excision.

8. *Spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

Membranous croup is either laryngeal diphtheria or a

streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci.

The *treatment of membranous croup*:—The patient should be isolated, and put to bed; the atmosphere of the room should be kept moist; the diet must be nutritious and easily digested; diphtheria antitoxin should be administered as soon as possible; alcohol, or strychnine, are indicated; local applications either hot or cold will relieve the pain, mild antiseptic solutions in the nose and throat are often used.

LARYNGOLOGY.

2. *Laryngismus stridulus* is a condition found in rhachitic children (generally under two years of age), and characterized by a reflex respiratory spasm of the larynx.

The *symptoms* of laryngismus stridulus are: The child holds his breath, the face becomes congested and cyanotic, the glottis is closed, inspiration is suddenly arrested, and ends in a shrill crowing sound; there may be spasms or convulsions; the attack is sudden, and may be repeated; there is no fever, coryza, nor cough.

Treatment: Cold water should be dashed on the face and chest; ammonia may be applied to the nostrils; an emetic may be administered, bromides or chloral should be given; attention must be paid to the diet and general hygiene of the child.

RHINOLOGY.

1. Some of the causes of epistaxis, dependent upon diseases affecting the composition and circulation of the blood, are: Hemophilia, pernicious anemia, leukemia, scurvy, purpura hæmorrhagica, cerebral congestion.

OTOLOGY.

1. Puncture of the drum membrane is performed for the purpose of relieving blood pressure, or of evacuating the fluid contents of the middle ear, for drainage; it is chiefly indicated in otitis media.

2. The two most frequent causes of deafness are: Inflammation of the middle ear, and impacted cerumen.

OPHTHALMOLOGY.

1. (*a*) A *yellow sclerotic* occurs in jaundice.

(*b*) A *bluish-white or pearl sclerotic* occurs in: Anemia, nephritis, and phthisis.

(*c*) An *inflamed or injected conjunctiva* occurs in: Gonorrheal or diphtheritic infection, in measles, hay fever, catarrhal influenza, coryza; sometimes in meningitis and facial paralysis.

2. May gives the following *varieties* of *iritis*, which also includes the *causes*:

(1) According to its *course*, Acute, Subacute, and Chronic.

(2) According to the *pathological products*, Plastic, Serous, Purulent, and Tuberculous.

(3) According to its *etiology*, Syphilitic, Rheumatic, Gouty, Diabetic, Gonorrheal, Tuberculous, Scrofulous, Traumatic, Sympathetic, Secondary, and Idiopathic.

3. Increase in the intraocular tension indicates glaucoma in any stage; dimness of vision is one of the earliest symptoms.

The importance of its early recognition is that treatment may be instituted at an early stage, and blindness be averted.

The best treatment is iridectomy.

If successful, sight is preserved, the progress of the disease is arrested, pain is relieved, and inflammatory symptoms subside.

NEUROLOGY.

1. *Epilepsy* is diagnosed by the aura, the sudden onset, the cry, the sudden loss of consciousness, the tonic convulsion, the biting of the tongue, the dilated pupils, and the urinary incontinence. In *hysteria*, the patients do not generally, hurt themselves.

Prognosis is not good; some cases may be ameliorated; a few recover, and but few die of the disease; in general, life is shortened by epilepsy.

2. *Multiple neuritis* is an inflammation of several nerve trunks, either simultaneously or in rapid succession.

The commonest causes are: Alcoholism, rheumatism, syphilis, mineral poisons (lead, arsenic, mercury), diabetes, some infectious diseases (malaria, leprosy).

3. The *treatment of migraine*: If possible remove the cause; examine for eyestrain, affections of the nose, indiscretions in diet, and mental and physical fatigue. Rest, in a darkened room, is necessary. The following drugs have been recommended: Phenacetin, caffein, morphine, the bromides, cannabis indica; also electricity.

PATHOLOGY.

1. *Degeneration* is a local order of metabolism, in which the protoplasm of the cell is gradually changed into a new material.

Infiltration is a local disorder of metabolism, in which new material is deposited in an organ or a tissue. The protoplasm of the cell is only affected mechanically.

2. The various kinds of chronic nephritis are the parenchymatous, and the interstitial.

In *chronic parenchymatous nephritis*, "both degenerative and proliferative changes are seen. The tubular epithelium is always more or less affected, showing signs of cloudy swelling, fatty degeneration, desquamation, and disintegration, most marked in the convoluted tubules, but also present in the loops and collecting tubules. The distribution of these changes is usually patchy, giving rise to mottling of the cortex. The lumina of the tubes may be dilated, and contain granular and fatty matters, and hyaline casts, the latter formed by coagulation of exudation in the tubules. The glomeruli may occasionally appear normal, but there is almost always some swelling and hyaline degeneration, together with some proliferation and desquamation, of the epithelium, so that they become highly cellular. Occasionally the glomerular changes may be more marked than the tubular; fatty degeneration of the glomerular and capsular epithelium may be prominent, or there may be swelling, proliferation, and desquamation of the epithelium, or both these changes may be combined. The glomerular vessels may be compressed, their endothelium degenerate, and they may be obstructed by leucocytes or by hyaline thrombi, and finally obliterated. Interstitial changes, though present, are not conspicuous, and consist of edema, and scattered foci of round-celled infiltration about the glomeruli and veins. Sometimes hemorrhages are evident in some of the glomeruli and the corresponding tubules. Lardaceous infiltration frequently accompanies parenchymatous nephritis."

In *chronic interstitial nephritis*, "the lesions are principally seen in the cortex; at first patches of cellular infiltration appear, then the intertubular connective tissue becomes increased and fibrous, with destruction of glomeruli and the corresponding tubules. The glomerular epithelium becomes swollen and desquamates, Bowman's capsules may be much thickened by concentrically arranged layers of nucleated fibrous tissue, and the Malpighian bodies in places may be converted into nodules of fibrous tissue, in others into cysts. The corresponding tubules undergo atrophy with disintegration of their epithelium; here and there multiplication, with convolution of the tubules, may be present, suggesting an adenomatous formation. There is everywhere an increase of the stroma, in the cortex and pyramids, between the tubules, and around the glomeruli and vessels, with pronounced round-celled infiltration or well-formed fibrous tissue, in which calcification may occur. The vessel walls are thickened, chiefly owing to an endarteritis. Lardaceous infiltration may accompany the interstitial nephritis."—(Hewlett's *Pathology*.)

3. *Ascites* is a collection of serous fluid in the peritoneal cavity.

The *causes* are: Portal obstruction, chronic inflammation of the peritoneum, abdominal tumors, cardiac disease, Bright's disease, chronic emphysema, anemia, cirrhosis of the liver.

4. The tumors which have epithelium as a physiological prototype, are: (1) Papilloma, (2) adenoma, (3) carcinoma.

Of these, the first two are benign; and carcinoma is malignant.

5. In *puerperal septicæmia* there is a general infection, microorganisms are present in the general circulation; and there is, of course, a local site of infection.

In *sapremia* there is a general infection caused by the absorption of toxins; but the putrefactive germs do not enter the blood.

6. Pus cells are chiefly leucocytes (generally of the polynuclear variety); some are alive but many are dead and swollen; infecting bacteria may also be present as well as fixed tissue cells.

BACTERIOLOGY.

1. The *streptococcus pyogenes* is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media), but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method.

The most important pathological conditions caused by it, are: Erysipelas, suppurations, malignant endocarditis.

It is often associated with diphtheria and tuberculosis.

HYGIENE.

1. In making a qualitative test of drinking water, the following impurities should be sought for: Lime, chlorine, nitrates, nitrites, ammonia, iron, lead, copper, pathogenic bacteria (including *Bacillus coli communis*), ova of parasitic intestinal worms.

3. The *period of incubation*, of measles, is ten to four-

teen days; of smallpox, ten to fourteen days; of diphtheria, two to seven days; of scarlet fever, some hours to six days; of whooping cough, four to fourteen days; of typhoid fever, five to thirty days. These figures are all approximate.

BULLETIN OF APPROACHING EXAMINATIONS †

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery		
Arizona*	Ancil Martin, Phoenix	Phoenix	July	6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July	14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	August	4
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July	7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July	14
Delaware	J. H. Wilson, Dover	Dover	June	16
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	July	14
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov.	11
Georgia	E. R. Anthony, Griffin	Atlanta		
Idaho	W. F. Howard, Pocatello	Boise	October	6

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Post-Typhoid Tuberculosis.—Ch. Lesieur and L. Jaubert considers it proved that typhoid fever and tuberculosis can coexist at any stage of either disease, but most of the infections that appear after the typhoid patient has begun to convalesce may be considered as infections that existed when the typhoid began, and were stimulated by that disease. Hence, it is only clinically post-typhoid. The prognosis is serious in such cases. The tuberculosis may affect any organs, the bones being frequently affected, the lungs, intestines, and meninges. Tuberculosis of the lungs may occur in any anatomical form. The best division of these cases is into slow and rapid cases, or into early and late tuberculosis. Early tuberculosis appears in the first days of convalescence, the first symptom being incomplete defervescence, and this is a very bad prognostic sign. The temperature rises at evening, anorexia, vomiting, and loss of flesh begin, and physical signs in the lungs soon appear. Evolution is now very rapid. If the trouble shows itself late in convalescence, the same series of phenomena begins, but progress is much slower, and treatment is much more successful. When a tuberculous pleurisy appears, the tuberculosis acts much as an injury would. The first symptoms are a renewed rise of temperature after defervescence of the typhoid fever. An abundant effusion is a factor favoring the tuberculous origin of the pleurisy. Laboratory diagnosis is of great value. The appearance of consolidation at an apex is also an aid to diagnosis. Lymphocytosis is also a characteristic of tuberculosis. The conclusions arrived at by the authors are that we should protect our typhoid fever patients from contact with tuberculous germs by isolation of the patient and the efficient disinfection of the wards.—*La Presse Médicale.*

THE OCCURRENCE OF EPILEPTIFORM ATTACKS IN DIABETES MELLITUS.*

By LEWIS A. CONNER, M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK AND THE HUDSON STREET HOSPITALS.

Although instances of the occurrence of convulsions in diabetes have been recorded from time to time for many years, such attacks are so rarely met with that, in the minds of most physicians, they have never come to be regarded as in any way a part of the symptomatology of that strange disease. Indeed, in the differentiation of the various forms of coma, the absence of convulsions has often been set down as a characteristic feature of the coma of diabetes, and by some of the older writers (Frerichs, Cyr) the categorical statement is made that convulsions never occur in such coma.

This feeling has been so general that when epileptiform attacks have been noted in the course of diabetes there has usually been a disposition to regard the association as fortuitous, or at least to look upon them as related only in an indirect way to the primary disease. In a good many cases this view has doubtless been the correct one. A certain proportion of such convulsive attacks are quite certainly of uremic nature and depend upon the frequently associated nephritis. In other instances the attacks may result from changes in the cerebral arteries, with subsequent hemorrhage or softening, or from an associated meningitis, etc. In still other cases the combination of a glycosuria and epileptiform seizures may depend upon some organic brain lesion which either directly or indirectly has disturbed the glycosuric center in the medulla. Finally, diabetes may, of course, develop in an epileptic subject.

After due allowance has been made, however, for all these possible causes there still remain a considerable number of recorded cases in which the clinical and post-mortem evidences are such as to leave no doubt that the convulsive seizures were directly related to the diabetes itself and were an expression of its toxic action upon the nerve cells.

The subject has a clinical interest greater than might at first be supposed, by reason of the fact that, although some of the epileptiform attacks occur only as a part of a terminal coma, a large proportion of them develop long before any signs of coma are manifest, and are of such a character, and are associated with such other symptoms, as to simulate closely the symptoms of a focal brain lesion. Such Jacksonian attacks may easily lead to serious errors in diagnosis. A case in which a misinterpretation of the symptoms was almost inevitable is that reported by Abbe, in which unilateral convulsions, hemiplegia, and aphasia, associated with acute mastoid disease on the opposite side, lead not unnaturally to the diagnosis of a brain abscess.

In the case about to be reported the symptoms, for the first few days of observation, were such as to suggest strongly the existence of some organic disease of the brain.

A. D., Italian girl, 16 years of age, single. Admitted to Hudson Street Hospital, December 12, 1907. Died, December 25, 1907. Family history negative for diabetes, tuberculosis, rheumatism, or distinct neuropathic tendencies.

Personal History.—No history of the usual diseases of childhood was obtainable. At four years the patient was ill for two months with convulsions of some kind, which are said to have been quite different from those of present illness. While never a strong, vigorous child, she has always been fairly healthy, and has never been acutely ill except for the above-mentioned attack. Menstruation began at fifteen, continued for three months at intervals of a month, and has been absent since. Three months ago patient had for a short time a slight discharge from the right ear. No history of injury to the head. For the past year she has had from time to time colicky pain in the abdomen, which has been less troublesome of late.

Present Illness.—The patient was as well as usual up to three weeks before admission to hospital. One morning, without known cause, she had a sudden attack of tremor of the right arm and right leg, which continued for about half an hour. There was no pain, but there was a stinging sensation as of "pins and needles" in the skin of the affected part. She did not lose consciousness; there was no movement of the face, head, or eyes. Similar attacks have since occurred several times every day and have become rather more frequent of late, though the movements of the right leg have been less pronounced. During this time it has been noticed that the patient drinks large quantities of water and gets up several times in the night to pass urine. There has been no appreciable loss of flesh, and no other symptoms of any sort have been noticed. The patient comes to the hospital only because of the persistence of one-sided convulsive attacks.

Physical Examination.—Medium-sized, well-developed, and well-nourished young girl. Face and mucous membranes of good color. Ears and nose normal, pupils equal, and react promptly to light. Tongue clean, throat slightly reddened, teeth in fair condition. Patient is conscious at all times and intelligent. No visible pulsation in vessels of neck, no glandular enlargements. Chest symmetrical and well developed, respirations regular and of normal rate. Lungs normal in every respect. Heart's action rapid and regular. Apex beat in the fifth space 10 cm. to the left of the midsternal line, impulse sharp and distinct. Relative dullness extends 2 cm. to the right of the midsternal line, up-

*Read at a meeting of the Practitioners' Society of New York, held April 3, 1908.

ward to upper border of the third rib, to the left 10.5 cm. from midsternal line. Heart sounds loud and clear; no murmurs. Pulse, rapid (110), regular, of small size, and of only fair force. Abdomen shows normal contours. No rigidity or tenderness, no masses to be felt. Liver dullness extends from upper border of sixth rib to the costal margin; edge not felt. Splenic dullness normal, edge not felt. Extremities—Marked weakness of the right arm with apparently some diminution of sensation. Tendon reflexes absent. Left arm normal. Right leg shows slightly diminished power compared with the left; both knee jerks absent. Plantar reflexes normal. Both eyegrounds appear normal.

During her stay of thirteen days in the hospital the convulsions numbered from four to twenty a day. Most, but not all, of them occurred during the daytime. They usually lasted from one to three minutes, but occasionally were of much longer duration. Once the twitchings continued for one hour and ten minutes.

For the first three or four days the convulsions affected only the right side of the body. Beginning in the arm, there were twitchings of the right arm and leg, and often, too, of the right side of the face, including the eyelids and forehead. The head and eyes were usually turned to the right at such times. During the last week of life the convulsions often involved the left side of the body as well as the right, and occasionally the twitchings were confined to the left side. At other times there would be twitchings of one side of the body, with a tonic spasm of the other side.

On December 18 the patient was examined by Dr. J. Ramsey Hunt, who found slight weakness of lower half of right side of face; marked weakness of right arm, leg, and foot; no disturbance of sensation, except inability to recognize objects held in right hand; loss of knee jerks and Achilles reflex on both sides, and eyegrounds normal except for some engorgement of the veins.

Until the last two days of her illness consciousness was preserved even during the attacks, and the intelligence was normal. On several occasions outbreaks of hysterical crying occurred. In some of the more severe convulsions a peculiar guttural sound was uttered, which seemed to indicate involvement of the laryngeal muscles.

It was difficult to say whether the attacks were associated with aphasia, as the patient neither spoke nor understood much English. During one attack of right-sided convulsions she complained of pain in the fingers of the right hand. Frequently the attacks would be followed by profuse sweating and by thirst. There was pronounced muscular weakness of right arm throughout, and during the last few days some weakness of the right leg and right side of the face as well.

The temperature remained normal or nearly so up to two days before death when it rose to between 104° and 105° and thereafter remained constantly high. At the same time the pulse became feeble and much more rapid (120 to 140) and patient became stuporous and finally comatose. The convulsions continued up to within a few hours of her death.

The breathing was quiet and regular throughout the illness. It was rapid only during and immediately after the convulsive attacks. There was at no time, even during the terminal coma, any suggestion of the Kussmaul air-hunger.

The condition of the urine is shown by the following chart:

Date	Diet	Amount 24 Hours	Reaction	Spec. Grav.	Albumin	Sugar	Acetone	Diacetic Acid	Oxybutyr. Acid
Dec. 12....	Mixed.....	.....	Acid....	1032	Faint trace	Positive.....		Absent.	
Dec. 14....	Carbohydrate free	900 c.c....	Acid....	1030	Faint trace	2.5%...	Present....	Present.	
Dec. 16....	Moderate restriction of carbohydrates.	1000 c.c...	Acid....	1020	Very faint trace.	1.2%...	Faint reaction.	Absent....	Absent.
Dec. 19....	Moderate restriction of carbohydrates.	1400 c.c...	Acid....	1026	Faint trace	2.5%...	Absent....	Absent....	
Dec. 21....	Moderate restriction of carbohydrates.	1800 c.c....	Acid....	1026	Faint trace	2%.....	Absent....	Absent....	Absent.
Dec. 24....	Moderate restriction of carbohydrates.	Incomp'te.	Acid....	1023	Very faint trace.	0.7%...	Present....	Slight reaction.	Absent.

A specimen of mixed urine of last twenty-four hours of life examined by Dr. Roper showed 2.7 per cent. glucose, marked reaction for acetone and diacetic acid, and negative reaction for oxybutyric acid.

Total nitrogen in 100 c.c. = 0.8 grams.

Ammonia nitrogen in 100 c.c. — 0.077 grams = 9.5 per cent.

Blood examinations: Red cells, 5,800,000; hemoglobin, 80 per cent.; color index, 75 per cent.

	Dec. 13.	*Dec.* 16.	*Dec.* 22.
Leucocytes	12,000	7,000	12,100
Polymorphonuclears	65%	63.5%	68%
Large lymphocytes	8%	3%	4%
Small lymphocytes	25%	32%	26%
Eosinophiles	2%	1.5%	2%

The fluid obtained by lumbar puncture was small in amount and normal in character, except for the presence of a small quantity of sugar.

Autopsy (by Dr. Symmers) five hours after death. (Condensed report.) Anatomical diagnosis. *Chronic diffuse inter- and intraacinar pancreatitis. Moderate periportal cirrhosis and fatty infiltration of liver. Cyanosis and moderate chronic parenchymatous degeneration of kidneys.*

Lungs—Normal. *Heart*—Normal. *Spleen*—Normal. *Stomach*—Moderate grade of chronic atrophic gastritis. *Liver*—Moderately enlarged; surface smooth; capsule tense and glistening. Scattered over the upper surface are several irregularly outlined yellowish patches which stand out in sharp

contrast to the dull blue color of the rest of the surface. On section the organ cuts readily; the substance is firm in consistency and diffusely bluish or bluish-red in color. Lobules well defined and slightly yellow in color. *Gall bladder*—Normal. *Pancreas*—Only the head and a small part of the body remain. The greater part of the body and the tail are represented by small islands of pancreas parenchyma embedded in quantities of fat. In these situations the form of the organ has been entirely lost. The head is relatively large, pale, and firm, and on section its lobules are pale, sharply outlined and project as rounded or conical nodules separated by small bands of pinkish tissue. This applies also to the small portion of the body which is left, although here the islands of pancreatic tissue are in places rather widely separated by bands of fatty tissue. The lumina of the arteries supplying the pancreas, as well as those in the immediate neighborhood, are small, their walls are thin and pliable, their intima smooth and pale.

Kidneys—Moderately enlarged, uniformly smooth, diffusely bluish with many reddish specks scattered over it. On section capsule strips readily leaving a smooth bluish surface. Cortex is pale and appears to be somewhat broadened. Markings very irregular. Parenchyma pale and yellow. Malpighian bodies frequently visible as distinct reddish points.

Intestines—Normal. *Genitalia*—Normal. *Arterial System*—Normal.

Brain—Dura matter irregularly, but strongly, adherent to calvarium. On removal brain appears to be well developed. The pia is pinkish in color and its venules in patches here and there are distinctly injected, but nowhere is there the slightest suggestion of exudate. The vessels at the base and the ventricles appear to be entirely normal. In the cortex gray and white matter are sharply differentiated. In the posterior part of the parietal lobe on both sides the white matter shows patches composed of numerous deep red points which do not scrape or wash away readily. Pons and medulla show no changes to the naked eye.

Microscopical Examination (Dr. Symmers).—*Liver*—The cells around the central veins show a moderate degree of vacuolation. The periportal connective tissue, especially around the medium-sized bile ducts, is distinctly, but not greatly, increased, is coarsely fibrillary and noncellular.

Pancreas—The connective tissue framework is very greatly increased and very diffusely distributed, surrounding the remains of the pancreatic lobules and insinuating itself between the individual groups of cells which enter into the formation of the acini. The connective tissue at the periphery of the islands of pancreatic cells is arranged in broad bands, is distinctly fibrillar in character, often wavy in outline, noncellular and supports in places large numbers of thin-walled blood-vessels, the lumina of which are choked by red cells. In the islands of parenchyma the cells of the acini are separated by distinct but rather delicate strands of pale noncellular connective tissue. The parenchyma islands are of various sizes and shapes and the cells in them vary in character. Some of the acini are lined with atrophied cells of the general type of secreting pancreas cells. In such acini the lumen is large. Other islands are made up partly, sometimes almost entirely, of very large acini lined with tall columnar cells with pale protoplasm and a small, richly chromatic, deeply-placed nucleus. These "acini" really seem to represent the remains of smaller ducts. In still other places the islands are composed of narrow, worm-like strands of very small cells closely packed together so that practically no lumen is visible. These cells have a comparatively large and richly chromatic nucleus and seem to represent an attempt on the part of the remaining pancreatic cells to regenerate. The islands of Langerhans are only occasionally to be made out as groups of flattened, evidently degenerate, cells arranged in a disorderly fashion and very indistinctly differentiated from the surrounding structures. One section shows a small lymphoid mass embedded in the substance of the organ.

Kidneys—These show a moderate degree of chronic parenchymatous degeneration and cyanosis.

Brain—Sections for microscopical examination were removed from one of the parietal lobes and from the pons and were stained in hematoxylin and eosin. In neither place are vascular or other changes present sufficient to account for the symptoms referable to the brain. The areas occurring in the parietal lobes and described as showing numerous red points in the white matter, are found, microscopically, to depend upon simple venous stasis.

The case is remarkable in many respects aside from the occurrence of Jacksonian attacks. The whole duration of the illness, from the appearance of the first symptom to her death, was but five weeks, and yet during almost the whole of this time the clinical picture, except for the convulsive paroxysms, was not at all that of severe diabetes. The quantity of urine was hardly more than normal, the amount of sugar excreted was small, the patient's nutrition was excellent and all the signs of a severe acidosis were lacking. Even in the terminal coma the urine contained no β-oxybutyric acid, the ammonia nitrogen was less than 10 per cent., and the peculiar and characteristic type of breathing, the Kussmaul "grosse Athmung," was entirely absent.

The mildness of the diabetic symptoms and prominence of the cerebral symptoms led me, during the first few days of observation, to look upon the case as probably one of organic brain disease, with disturbance of the glycosuric center, rather than one of true diabetes. But the absence of all confirmatory signs of abscess, tumor, meningitis, etc., and, as Dr. Hunt pointed out, the existence of other nervous symptoms common in diabetes (absence of patellar and Achilles reflexes) compelled me gradually to abandon this view. The post-mortem findings in the case and its close resemblance to some of the published cases leave no room for doubt that it was one of true pancreatic diabetes and that the cerebral symptoms were the direct result of the diabetic poison. Both organic disease of the brain and nephritis could be excluded with certainty.

A second instance of the occurrence of Jacksonian convulsions in diabetes I am enabled to report through the courtesy of Dr. James C. Johnston under whose observation the case came.

A man, fifty-nine years old, with general arteriosclerosis and doubtful history of syphilis had had severe diabetes for at least three years. The urine often contained 6 to 7 per cent. of sugar, which however, could be greatly reduced when the patient was willing to carry out a proper regimen. During this time he had two severe attacks of xanthoma diabeticorum* coincident with lapses of treatment of the diabetes. In the spring of 1896, after having been in fairly good general condition for some months, the diabetic symptoms became worse, the urinary

*This aspect of the case has been reported by Dr. Johnston, in the *Journal of Cutaneous and Genito-Urinary Diseases*, Vol. XII., 1894, p. 205.

sugar increased to about 6 per cent., and the patient developed attacks of convulsive twitchings affecting at first only the right side of the tongue. After the first two days the attacks involved also the right side of the face, including the eyelids and forehead. The convulsions, however, never extended to any of the extremities nor was consciousness lost during the seizures. There was no aphasia and no loss of power was recognized in the affected muscles. The attacks, which lasted only a few minutes, increased in frequency until at the end of three or four days they became almost continuous and interfered seriously with the taking of nourishment. Sedative drugs, including morphine, had no effect in controlling the paroxysms. The urine gave no evidences of nephritis. No examination was made for the presence of the acetone bodis. Five days after the onset of the convulsions the patient gradually passed into a state of stupor and died in coma forty-eight hours later. No autopsy was obtained.

In this case it is impossible, in the absence of a post-mortem examination, to exclude the possibility that the symptoms may have been due to some gross lesion of the brain; but the clinical picture of the case has so much in common with that of the other recorded cases that it seems fair to regard it as of the same class.

I have attempted to collect from the literature all the cases of convulsions occurring in diabetes in which the reports were sufficiently definite to be of value and in which it could be determined with reasonable certainty that the attacks were directly related to that disease. These cases (twelve in all) seem to me to be of sufficient interest to justify their presentation here in condensed form.

Scheube.[1] Man, twenty-seven years old. Symptoms of diabetes for about six months. In hospital for two months, on diet chiefly of meat, with little improvement in sugar and with loss of weight. While in the terminal *coma dyspnoicum* patient had a single general clonic convulsion of short duration.

Lépine and Blanc.[2] Man, thirty-nine years of age. One brother epileptic. Diabetes of severe type for ten months (15 liters of urine and 700-800 grams of sugar daily). Some improvement under treatment. Gradual development of weakness of right arm and leg which in two weeks amounted to complete hemiplegia. Also immediately after onset of weakness patient began to have convulsive attacks in the right arm, leg, and face. The convulsions returned every three or four hours and lasted five or six minutes. Consciousness was preserved during the paroxysms. Three weeks after onset (when admitted to hospital) he had begun to have difficulty of speech. The convulsions then occurred about once a day and lasted two minutes. They affected the right arm and leg and right side of face, including the eyelids. Tongue not involved. The hemiplegia included the right side of face and half of tongue. The aphasia persisted, the mind was much enfeebled. After period of somnolence for some weeks patient began to improve mentally, and hemiplegia became much less pronounced. During this time he gained in weight and was excreting very little sugar. Soon afterward he developed symptoms of pulmonary tuberculosis and died in three months. The autopsy showed no gross lesion of the brain, but microscopically in the left ascending parietal convolution there was "almost complete disappearance of the pyramidal cells with changes in the neuroglia and dilatation of the capillaries.

Lépine.[3] Woman, fifty-eight years of age. Diabetic for five years. After several days of headache patient had an attack of syncope followed by pronounced "trembling" of the upper extremities. Two days later sudden loss of consciousness and clonic convulsions, most marked in the legs. Attack lasted ten minutes. On the following day a second general convulsion. During the next two days there was constant "agitation" and occasional hallucinations of sight. The daily quantity of urine amounted to 5 liters, the sugar to 300 grams. The urine also contained β-oxybutyric and formic acid. Five days later patient sank into coma and died.

Abbe.[4] An active, healthy man of forty-four years developed a severe influenza complicated by a suppurative otitis media of the left side. He continued to lose flesh and strength and a few days later began to notice a marked increase in frequency of micturition and in quantity of urine passed. A few weeks later he noticed a growing difficulty in uttering certain words. Two months after onset he began to have attacks of Jacksonian epilepsy and entered hospital where it was found that the urine was moderately increased in amount (40 to 86 ounces) and contained about 30 grains of sugar to the ounce. No albumin nor casts. The epileptiform attacks occurred several times a day and began with numbness in right side of body, followed by convulsive movements of right leg and arm and sometimes of right side of face. After the attacks there was weakness of right arm and leg, transient aphasia and diminished sensation on the affected side. The knee jerks were lost. Consciousness was usually preserved. Sixteen days after onset of the Jacksonian attacks inflammation of left mastoid developed rapidly and on following day required operation. The severe right-sided convulsions continued and the aphasia became more pronounced. Three days later, upon the supposition that a brain abscess might have formed, the left side of the skull was opened but nothing was found. The convulsions continued, became more general and more severe and five days later patient died in coma. The autopsy showed a perfectly normal brain and a fibroid and greatly atrophied pancreas.

Kraus, Fr.[5] Man, fifty-one years of age. Diabetes for one and a half years. Daily urine from three to six liters, sugar from 5 to 7 per cent., no ferric chloride reaction. After several days during which the patient appeared silent and anxious he became suddenly unconscious and developed clonic spasm first of the left upper extremity, then of other groups of muscles, until finally a general epileptiform attack resulted. The whole attack lasted several minutes. The next day there were numerous similar attacks. During these the patient was completely unconscious. In the free intervals consciousness became less and less full until there was continuous coma. No Kussmaul air-hunger or "grosse Athmung." Temperature subnormal. No acetone odor to breath. After several days the attacks became less frequent, and finally, with the coma, disappeared entirely. No $Fe\,Ch_3$ reaction at any time. No β-oxybutyric acid. No alkaline treatment. A few days later patient developed a pneumonia and died.
